Biographical Sketch – Elias Abrutyn

Elias Abrutyn, co-editor of this, the 4th Edition of *Bacterial Infections of Humans*, died unexpectedly on February 22, 2007, at the age of 66 years. Eli was an extremely enthusiastic and energetic collaborator in developing this edition. His knowledge of infectious diseases of both literature and current activities in the field contributed significantly to the quality of this textbook.

Elias Abrutyn
1940–2007

Eli was born on April 15, 1940, in New Jersey and received his BA degree from the University of Pennsylvania in 1960. He attended the University of Basil in Basil, Switzerland from 1960 to 1963 and was awarded his MD from the University of Pittsburgh in 1966. He was an intern and medical resident at the Hospital of the University of Pennsylvania in Philadelphia from 1966 to 1968. He joined the Epidemic Intelligence Service at the Centers for Disease Control and Prevention in 1968 and worked in the Field Services Branch, Immunization Division, where he became the acting assistant director. In 1970, he assumed the Chief Medical Residency position at the University of Pennsylvania Veterans Administration Medical Center. In 1971, he was a post-doctoral Fellow in Infectious Diseases at the Hospital of the University of Pennsylvania. In 1972, he became an assistant professor of Medicine at the University of Pennsylvania School of Medicine and in 1984 was appointed an adjunct professor of Medicine at the University of Pennsylvania School of Medicine, a position he held until 1996. From 1982 to 1997, he was also a professor of medicine at the Medical College of Pennsylvania. From 1989 to 2005, he was a senior scholar in the Clinical Epidemiology Unit and then the Department of Epidemiology and Biostatistics at the University of Pennsylvania School of Medicine. From 1991 to 1996, he was associate dean for Veteran's Affairs at the Philadelphia Veterans Administration Medical Center. In 1996, he became professor of medicine with tenure at the Medical College of Pennsylvania Hahnemann University and then Vice Chairman of the Department of Medicine. From 1998 to 2000, he was also the interim chairman of the Department of Medicine at the Medical College of Pennsylvania Hahnemann University. In 2000, he became the Associate Provost and Associate Dean for Faculty Affairs at

Drexel University College of Medicine and the Allegheny University of Health Sciences. In 2002, he also assumed the position of Interim Chief of Infectious Diseases at Drexel University College of Medicine. Eli had his boards in Internal Medicine and Infectious Diseases.

He was a member of and held offices in a number of prestigious professional societies including the American College of Physicians, American Medical Association, American Federation for Medical Research, American Society for Microbiology, American Board of Internal Medicine, Association for Practitioners in Infection Control, Association of Professors in Medicine, Hospital Infections Society (England), Infectious Diseases Society of America, International Society for Cardiovascular Infectious Diseases, and the Society for Healthcare Epidemiology of America. Among his accolades, Eli was past president of the Society for Healthcare Epidemiology of America, a master of the American College of Physicians Society for Internal Medicine, a Fellow of the Infectious Disease Society, and a member of the council of the International Society of Cardiovascular Diseases. Additionally, he belonged to a number of local and regional societies. He was an associate editor of Annals of Internal Medicine and was on the editorial board of Infectious Disease Practice, and Clinical Performance in Quality Healthcare.

He was a consultant for a number of national and local organizations, including the chair of several National Institutes of Health committees, and on a committee to review a program for controlling emerging infectious diseases at the Centers for Disease Control and Prevention. He was a reviewer of manuscripts for 20 different scientific journals. He was a member of a number of national and local scientific committees and was the chairman of a large number of these committees.

Over the years, Eli had a number of grants, primarily dealing with infectious diseases. He was author and/or co-author of 103 publications in peer-reviewed journals, primarily reporting on infectious diseases, including urinary tract infections, infective endocarditis, and influenza. He also published on antibiotics, public health surveillance, hospital epidemiology, and health education. He wrote a number of editorials published in peer-reviewed journals. He was senior author of a book “Infection Control Reference Service” that is considered one of the authoritative texts in the field, in addition to being co-editor of this text book. He was author and co-author of 46 chapters in textbooks and newsletter articles dealing primarily with infectious diseases. He also wrote a number of commentaries and many abstracts, and gave presentations at national and international meetings.

Eli was well respected by his peers and enjoyed teaching on topics in internal medicine with emphasis on infectious diseases. He was a scholar, a careful researcher, well read on all infectious disease topics, and recognized as a leader. He will be missed by his students, colleagues, and friends.

Preface

In Memoriam of Alfred S. Evans

The third edition of *Bacterial Infections of Humans* is dedicated to Alfred Spring Evans, who died on January 21, 1996, 2 ½ years after a diagnosis of cancer. Al was the senior editor of this textbook, which he founded with Harry Feldman in 1982.

Al was a clinician, epidemiologist, educator, catalyst for biomedical research, historian, author, speaker, seeker of the truth, sincere friend of students, sports enthusiast, traveler, and truly a man of all seasons. He was a devoted husband to Brigette Klug Evans, father of three children, and grandfather of four.

Alfred S. Evans
1917–1996

Al was born in Buffalo, New York, on August 21, 1917, to Ellen Spring and John H. Evans, M.D., one of the United States's first anesthesiologists and an early researcher in the field of oxygen therapy. He received his undergraduate training at the University of Michigan; was awarded an M.D. degree in 1943 from the University of Buffalo; interned in Pittsburgh, Pennsylvania; and performed his medical residency at the Goldwater Hospital in New York City. He was in the United States Army from 1944 to 1946, assigned as a public health officer to a base in Okinawa, Japan. It was there that he met Drs. Albert Sabin and John R. Paul, who came to Okinawa to test a new Japanese encephalitis vaccine. Al was invited by Dr. Paul to come to Yale University to work on the identification of the cause of infectious mononucleosis. He accepted this invitation and became an associate professor of medicine in the Department of Medicine from 1946 to 1950. He was then called back to active duty in the Army and acted as chief of the Hepatitis Research Laboratory in Munich, Germany. It was there that he met his future wife.

In 1952, he joined the University of Wisconsin Medical School faculty and was professor and chairman of the Department of Preventive Medicine. In 1959 he also became director of the state Laboratory of Hygiene. He took a sabbatical leave in 1960 to study for his M.P.H. degree, which he received from the University of Michigan in 1961. In 1966 he accepted the position of John Rodman Paul Professor of Epidemiology at Yale University. Additionally, he became the director of the WHO's Serum Reference Bank at Yale. He remained active as a teacher and researcher until 1988 when he became an emeritus professor. He retired from Yale in 1994.

Al was dedicated to teaching both undergraduate and graduate students, and his expertise included a full range of topics in preventive medicine, public health, epidemiology (both applied and clinical), infectious diseases, and other related subjects. He was one of the founders and the first director of the Graduate Summer Session in Epidemiology, which was first held in the summer of 1965 at the University of Wisconsin. He remained on its faculty when it was held at the University of Minnesota from 1967 to 1987, and then at the University of Michigan School of Public Health from 1988 through the summer of 1994. During his 29 years of association with the Graduate Summer Session, he was not only a lecturer, primarily in epidemiology and infectious diseases, but was also an active participant on the Planning Committee and was the unofficial social chairman for the 3-week session.

Al was a popular lecturer who used expected and unexpected visual aids and injected humor throughout his lectures. He enjoyed teaching, and his students were eager recipients, greatly stimulated by his teaching, who frequently acknowledged his excellence with words, deeds, and appropriate awards, such as the Bedpan Award for Clinical Teaching given at the University of Wisconsin in 1952. As a teacher he constantly looked for new methods of presenting information to students. He was dedicated to the method of problem-oriented sessions and developed his own infectious disease case studies, which he would incorporate into his lectures. Additionally, he was a popular guest lecturer at universities and institutions in the United States and throughout the world. He was never too busy for his students and provided ongoing consultation concerning their training and careers.

His research ranged over broad fields of infectious disease as well as public health and epidemiology, with an emphasis on the Epstein–Barr virus and the relationships between cancer and infectious agents. He was the author or coauthor of more than 230 scientific, peer-viewed publications covering a broad area of topics, including such titles as "Sneezes, Wheezes, and Other Diseases" (1961), "Farm Injuries" (1958 and 1961), and "The Instant-Distant Infection" (1966). He was a medical historian, writing essays on John Evans, Austin Flint, and Max von Pettenkofer. He constantly promoted the incorporation of presentations on medical or public health history in the programs of various societies and training programs. He was an active supporter of Yale's historic Beaumont Medical Club.

Al firmly believed in the importance of accuracy in investigations, whether in the laboratory or in the field. His initial involvement in a field investigation incorporated comprehensive descriptive epidemiology that, when appropriate, was followed by methodical and carefully conceived analytic epidemiological methods. He was innovative in the use of observational field studies, which is reflected in his studies of the Epstein–Barr virus. Al constantly promoted the development and use of serum banks, as reflected by the WHO Serum Reference Bank at Yale. There are numerous examples of how this facility made significant contributions to Al's studies of infectious mononucleosis, other infectious diseases, and, more recently, HIV/AIDS. He made significant contributions to the concepts of disease causation and researched and reworked Koch's postulates. In this regard, he acknowledged the important contributions that Jakob Henle made to the topic and renamed Koch's postulates the Henle–Koch postulates.

He was author or coauthor of five well-received textbooks: *Viral Infections of Humans* (which in 1977 received The American Medical Writers' Association award for the best book written for physicians), *Bacterial Infections of Humans, Methods in Observational Epidemiology, Causation and Disease: A Chronological Journey*, and *Symposium on Latency and Masking in Viral and Rickettsial Infections*. He was also an editor of the *Yale Journal of Biology and Medicine*. He was a consultant to the WHO, the Pan American Health Organization, the United States Public Health Service, and the National Aeronautics and Space Agency and worked specifically with the space program in establishing the infection quarantine programs for the Apollo 13 space mission. He frequently consulted with numerous Ministries of Health in other countries, including Czechoslovakia, Kuwait, France, Spain, Taiwan, the Philippines, and Vietnam.

Al remained current with the medical literature, applied new technology in his own research, and brought appropriate new information into his lectures and writings. He constantly acquainted his colleagues and students with pertinent new written information culled from the current medical literature.

He belonged to and was an avid supporter of a number of societies, including the American Epidemiological Society, for which he served as secretary-treasurer (1968–1972) and president (1973); The American College of Epidemiology, of which he was one of the cofounders and later served as president

(1990); The Society of Epidemiologic Research; The Infectious Disease Society of America; The Society of Medical Consultants to the Armed Forces, for which he served as president (1983); and the American Public Health Association (where he was president of the Epidemiology Section). He was also a fellow of the American Association for the Advancement of Science.

Al received numerous prestigious awards and lectureships, including the Thomas Parron Lecturer and Award, University of Pittsburgh (1977); the Thomas Francis Lectureship, University of Michigan School of Public Health (1986); the Abraham Lilienfeld Lectureship, American College of Epidemiology (1986); the First Harry Feldman Memorial Lectureship, American Epidemiological Society (1987); the John R. Seal Award, The Society of Medical Consultants to the Armed Forces (1987); the W.B. Harrington Lecture and Award, University of Buffalo (1988); the Abraham Lilienfeld Award, Epidemiology Section, American Public Health Association (1990); and the Kass Lecturer, The Infectious Disease Society of America (1995). He was a renowned poet, but never published any of his works. He enjoyed reciting them in the classroom, in private discussions, and at social events.

During his life, he set standards to which others will aspire. The world is richer for the activities of Alfred Spring Evans, and we will all be better scientists and humanitarians because of his contributions.

The contents of this book were written by experts in the specific topics of each chapter, many of whom Al knew personally. The quality of the chapters reflects the multiple contributions that Alfred Spring Evans made to each of our professional lives.

Contents

Chapter 1 **Epidemiological Concepts** 1
Alfred S. Evans

1. Introduction 1
2. Definitions and Methods 2
3. Epidemics and Their Investigation 7
4. Agent 11
5. Environment 14
6. Host 15
7. Routes of Transmission 17
8. Pathogenesis 20
9. Incubation Period 21
10. Immune Response 22
11. Patterns of Host Response 26
12. Diagnosis of Bacterial Infections 34
13. Proof of Causation 38
14. Control and Prevention 38
15. References 46
16. Suggested Reading 50

Chapter 2 **Public Health Surveillance** 51
Philip S. Brachman

1. Introduction 51
2. History 51
3. Use of Surveillance 52
4. Data Sources 53
5. Routine Surveillance 56
6. Reporting 56
7. Special Surveillance 60
8. Data Analysis 62
9. Reports 65
10. Evaluation 66
11. Limitations of Surveillance 66
12. References 66
13. Suggested Reading 67

Chapter 3 **Molecular Epidemiology** 69
Lee W. Riley

1. Introduction 69
2. Definitions 69
3. Methodology 70
4. Epidemiologic Problems Addressed by Genotyping Techniques 79
5. Summary 85
6. References 85
7. Suggested Reading 88

Chapter 4 **The Epidemiology of Bacterial Resistance to Antimicrobial Agents** 91
Fred C. Tenover and John E. McGowan, Jr.

1. Introduction 91
2. Historical Background 91
3. Mechanisms of Resistance 92
4. Epidemiology of Antimicrobial Resistance 98
5. Organisms of Special Importance 99
6. Unresolved Problems 100
7. References 101
8. Suggested Reading 104

Chapter 5 **Anthrax** 105
Philip S. Brachman and Arnold F. Kaufmann

1. Introduction 105
2. Historical Background 105
3. Methodology 106
4. Biological Characteristics of the Organism 107
5. Descriptive Epidemiology 108
6. Mechanisms and Routes of Transmission 112
7. Pathogenesis and Immunity 112
8. Patterns of Host Responses 113
9. Control and Prevention 115
10. Unresolved Problems 116
11. References 117
12. Suggested Reading 119

Chapter 6 **Bacterial Foodborne Disease** 121
Heather Green, Jon Furuno, Amy Horneman, and J. Glenn Morris, Jr.

1. Introduction 121
2. Historical Background 122
3. Foodborne Disease Outbreak Surveillance 123
4. Etiologic Patterns 126
5. *Staphylococcus aureus* 127

6. *Bacillus cereus* 129
7. *Clostridium perfringens* 132
8. "Noncholera" *Vibrio* Species 136
9. *Aeromonas* Species 142
10. *Plesiomonas* 145
11. Control and Prevention 147
12. Unresolved Problems 149
13. References 149

Chapter 7 **Botulism** 159
Patricia A. Yu, Susan E. Maslanka, Michael E. St. Louis, and David L. Swerdlow

1. Introduction 159
2. Historical Background 159
3. Methodology 160
4. Biological Characteristics of the Organism 162
5. Descriptive Epidemiology 162
6. Mechanisms and Routes of Transmission 166
7. Pathogenesis and Immunity 167
8. Patterns of Host Response 168
9. Prevention, Control, and Treatment 170
10. Bioterrorism 172
11. Unresolved Problems 172
12. References 172
13. Suggested Reading 176

Chapter 8 **Brucellosis** 177
Edward J. Young

1. Introduction 177
2. Historical Background 177
3. Methodology 178
4. Biological Characteristics of the Organism 179
5. Descriptive Epidemiology 180
6. Mechanisms and Routes of Infection 183
7. Pathogenesis and Immunity 183
8. Patterns of Host Response 184
9. Control and Prevention 185
10. Unresolved Problems 185
11. References 185

Chapter 9 ***Campylobacter* Infections** 189
Ban Mishu Allos

1. Introduction 189
2. Historical Background 189

3. Methodology 191
4. Proof of Causation and Biological Characteristics of the Organism that Affect the Epidemiological Pattern 193
5. Descriptive Epidemiology 194
6. Mechanisms and Routes of Transmission 197
7. Pathogenesis and Immunity 198

CHAPTER 1

Epidemiological Concepts

Alfred S. Evans[1]

1. Introduction

Epidemiology is the study of the distribution and determinants of health-related states, conditions, or events in specified populations and the application of the results of this study to the control of health problems.(1) It is a quantitative science concerned in infectious diseases with the circumstances under which disease processes occur, the factors that affect their incidence and the host response to the infectious agent, and the use of this knowledge for control and prevention.(2) It includes the pathogenesis of disease in both the community and the individual. For infectious diseases, one must study the circumstances under which both *infection* and *disease* occur, for these may be different. Infection is the consequence of an encounter of a potentially pathogenic microorganism with a susceptible human host through an appropriate portal of entry and usually involves a demonstrable host response to the agent. Exposure is the key factor, and the sources of infection lie mostly outside the individual human host, within the environment, or in other infected hosts. Disease represents one of the possible consequences of infection, and the factors important in its development are mostly intrinsic to the host, although the dosage and virulence of the infecting microbe play a role. These intrinsic factors include the age at the time of infection, the portal of entry, the presence or absence of immunity, the vigor of the primary defense system, the efficiency and nature of humoral and cell-mediated immune responses, the genetic makeup of the host, the state of nutrition, the presence of other diseases, and psychosocial influences. These factors that result in the occurrence of clinical illness among those infected have been called the "clinical illness-promotion factors,"(3) and many of them remain unknown. The host responses can include death, the classic clinical features of the disease, mild or atypical forms, subclinical and inapparent infections, and the carrier state, which may exist in the absence of a detectable host response. While the clinician is primarily concerned with disease, the epidemiologist is interested in both infection and disease. Infection without disease is a common phenomenon, so that a study limited to clinical illness alone would give an incomplete epidemiological picture and would be a poor basis for control and prevention.(4) A full understanding involves the pathogenesis of the process leading to clinical disease both in the community and in the individual.

The concepts of epidemiology in bacterial infections are very similar to those of viral infections as expounded in the companion volume, *Viral Infections of Humans*,(5) so there will be overlap and repetition in this volume. Some of the differences between viral and bacterial infection include the intracellular position of all viruses, their smaller size, the requirement of living tissues for viral multiplication, the ease with which many viruses are spread by respiratory routes or by insect vectors, the relatively high order of immunity following viral infection, the usefulness of serological tests for the diagnosis of most viral infections, and the failure of viral infections to respond to antibiotic therapy. Highly sensitive and specific molecular methods are being increasingly employed to define the agent and the host response to it.(6–8)

Many concepts and methods of epidemiology apply to both infectious and noninfectious diseases, and there should be no essential dichotomy between the two.(9) In general, epidemiology can be regarded as the development, pathogenesis, and expression of infection and disease in a community in much the same way as clinical

Alfred S. Evans • Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, Connecticut 06510, USA (†Deceased).

It should be noted that this chapter is the original introductory chapter as written by Alfred S. Evans for the first edition in 1982.

[1]Deceased. Dr. D. Scott Schmid, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia, assisted in revising Section 10, Immune Response, after Dr. Evans' death.

A.S. Evans, P.S. Brachman (eds.), *Bacterial Infections of Humans*, DOI 10.1007/978-0-387-09843-2_1,

medicine is concerned with the development, pathogenesis, and expression in the individual. This book will attempt to cover both these aspects. While the "epidemiology of infectious diseases" has disappeared from the curriculum of many schools of medicine and public health in developed countries, the current epidemic of the acquired immunodeficiency syndrome (AIDS) has reawakened interest in the subject. In addition, the emergence of new diseases such as Legionnaires' disease, Lyme disease, the toxic shock syndrome and the development of antibiotic-resistant pneumococci and tubercle bacilli, the appearance of erythrogenic streptococci ("flesh-eating" streptococci) and a new cholera strain termed 0139, foodborne outbreaks of *Escherichia coli* O157:H7, and a large waterborne outbreak of cryptosporidiosis are among the "emerging infections" that continue to pose challenges to epidemiologists[10] and for which the Centers for Disease Control and Prevention (CDC) are developing preventive strategies.[11] It is becoming apparent that in developed countries, the continuing, and in some instances the increasing, importance of infectious diseases is causing concern among public health authorities.

In developing countries, infectious diseases are still a major cause of morbidity and mortality, and efforts are in progress to develop training programs in epidemiology and in surveillance in such areas. The Field Epidemiology Training Program of the CDC is a fine example of this effort. Several recent texts address the problems of surveillance.[12–16]

2. Definitions and Methods

2.1. Definitions

A working understanding of the terms commonly used in epidemiology and infectious diseases may be helpful to the student, microbiologist, and clinician unfamiliar with them. They are derived from those in *A Dictionary of Epidemiology*,[1] *Viral Infections of Humans*,[5] and the American Public Health Association handbook entitled *Control of Communicable Diseases Manual*.[17]

Attack rate or case ratio: This ratio expresses incidence rates in population groups during specified time periods or under special circumstances such as in an epidemic. It is often expressed as a percent (cases per 100). The *secondary attack rate* is the proportion of persons who develop infection within an appropriate incubation period after exposure to a primary case divided by the number exposed. The groups so exposed are frequently family members or persons located in an institution.

Carrier: A carrier is a person, animal, or arthropod who harbors a specific infectious agent in the absence of clinical illness with or without a detectable immune response. The carrier state may reflect carriage of the organism in the incubation period before clinical symptoms appear, during an apparent or inapparent infection (healthy or asymptomatic carrier), or following recovery from illness; it may be of short or long duration (chronic carrier), and it may be intermittent or continuous. Carriers may spread the infectious agent to others.

Case-fatality rate: Number of deaths of a specific disease divided by the number of cases $\times$ 100.

Cell-mediated immunity: This term has been used previously to designate immune mechanisms largely dependent on lymphocyte activity and in contrast to "humoral immunity." As T lymphocytes are now recognized as playing an important role in both, the term *T-cell immunity* is being more widely used.

Chemoprophylaxis: Administration of a chemical or antibiotic to prevent infection or to prevent the development of disease in a person already infected.

Colonization: Multiplication of an organism on a body surface (e.g., skin, epithelium, mucus membrane) without evoking a tissue or immune response.

Communicable period: Time during which a person (or animal) is infectious for another person, animal, or arthropod.

Endemic: This term denotes the constant or usual presence of an infection or disease in a community. A high degree of endemicity is termed *hyperendemic*, and one with a particularly high level of infection beginning early in life and affecting most of the population is called *holoendemic*.

Epidemic: An epidemic or outbreak is said to exist when an unusual number of cases of a disease occur in a given time period and geographic area as compared with the previous experience with that disease in that area. For diseases already present in the community, it is necessary to know the number of existing cases (prevalence) as well as new cases (incidence) to determine whether an increase has occurred. The definition of increases or excess cases is arbitrary and will vary from disease to disease. See Section 3 for further discussion.

Host: A person, animal (including birds), or arthropod in which infectious agents subsist or infect under natural conditions. In this book the term will most often refer to the "human host" unless otherwise stated.

Immunity: The specific resistance to an infectious agent resulting from humoral and local antibodies and from cell-mediated responses constitutes immunity. Immunity may be acquired through natural infection, by active immunization, by transfer of immune factors via the placenta, or by passive immunization with antibodies from another person or animal. The immune state is relative and not absolute, is gov-

erned largely through genetic control, and may be altered by disease- or drug-induced immunosuppression.

Immunodeficiency: A state representing impairment of the immune system of the host that affects its ability to respond to a foreign antigen. This may result from an inherited defect, or an acquired one such as a result of the disease itself, or of immunosuppressive drugs or an infectious agent that depresses the immune system. The human immunodeficiency viruses (HIV-1 and HIV-2) are the major examples of the latter.

Incidence rate: The number of new events (specific infection or disease) occurring in a given time period in a given population as the numerator and the number of susceptible persons in that population exposed to the agent as the denominator. This is usually stated as cases (or infections) per 100, 1,000, or 100,000. This rate may be adjusted for an age- or sex-specific numerator and denominator or any other characteristic of interest. Laboratory procedures may be required for numerator data on new infections, as measured by isolation of the agent or by antibody rises, or by both. They may also be required to identify those actually at risk in the denominator, i.e., those lacking antibody; other means of refining the denominator would be by eliminating adults in calculating rates of childhood diseases or eliminating those with a valid history of having had the disease.

Incubation period: The incubation period is the interval between exposure and the appearance of the first detectable sign or symptom of the illness. Ill-defined exposure to a source of infection or exposure to persons without apparent illness may obscure the starting point of the incubation period, and vague, premonitory, or prodromal signs of illness may obscure its termination point. The best estimate is often derived from single exposures of short duration to a clinical case or established source of infection (e.g., air, food, water, arthropod vector) and the development of the first characteristic or classic features of the disease. Experimental infections in volunteers give well-defined incubation periods, but these may not always be the same as under natural conditions. See Section 7 for further discussion.

Index case: This is the index or primary case of an illness in a family, group, institution, or community that may serve as a source of infection to others.

Infection: Infection represents the deposition, colonization, and multiplication of a microorganism in a host and is usually accompanied by an immune response. Infection may occur with or without clinical illness.

Isolation: This is a term applied to the separation of infected persons in such places and/or under such conditions as to prevent contact or airborne transmission of the infectious agent to others during the period of communicability. Infection control practice in hospitals as recommended by the CDC has divided isolation into two tiers of isolation precautions. The first tier is known as *standard precautions* and the second tier *transmission-based precautions*. Hand washing remains a prime preventive measure in regard to nosocomial infections.

Morbidity rate: An incidence rate in which the numerator includes all persons clinically ill in a defined time and population and the denominator is the population involved or a subunit thereof, usually expressed as the number of cases per 100,000 persons at risk.

Mortality rate: The same as morbidity rate except the numerator consists of deaths. This may be the total number of deaths in a population group (crude mortality rate, usually expressed as deaths per 1,000) or deaths from a specific disease (disease-specific mortality, usually expressed as deaths per 100,000).

Nosocomial infections: This term refers to infections that develop after entry into a hospital or other health care institutions and that are not present or incubating at the time of admission or the residual of an infection acquired during a previous admission.

Pathogenicity: The ability of an infectious agent to produce disease in a susceptible host. Some nonpathogenic agents can become pathogenic in an immunocompromised host such as persons infected with HIV.

Prevalence rate: The ratio of the number of persons in a defined population who are affected with the disease at any one time as the numerator and the exposed population at that point as the denominator. If this is based on the frequency of cases at a moment in time, then the term *point prevalence* is used. If it reflects the proportion of persons affected over a longer period, then the term *period prevalence* is employed. Most infectious diseases are acute and short lived, so that prevalence rates are not commonly used. The use of prevalence rates is more relevant to more protracted illnesses such as subacute bacterial endocarditis, tuberculosis, and leprosy, or to reflect carrier states that may persist for months or years. Prevalence rates reflect incidence times duration of disease. In seroepidemiological usage, the term *prevalence* denotes the presence of antigen, antibody, or another component in the blood.

Quarantine: The restriction of persons or animals exposed to an infected source during the incubation period for that disease to observe if the disease develops in order that other persons will not be exposed to the infectious agent during that period.

Reservoir: A person, animal, soil, or other environment in which an infectious agent normally exists and multiplies and which can be a source of infection to other hosts.

Surveillance: As concerns public health, surveillance is the systematic collection of data pertaining to the occur-

rences of specific diseases or health-related conditions, the analysis and interpretation of these data, and the dissemination of consolidated and processed information to contributors to the program and other interested persons for purposes of control and/or prevention (see Chapter 2 for detailed discussion and Cutts et al.[12] for a World Health Organization definition, as used in the Expanded Programme in Immunization). *Serological surveillance* is the identification of current and past infection through measurement of antibody or of antigen in serum from representative samples of the population or other target groups.

Susceptibility: A state in which a person or animal is capable of being infected with a microorganism. The lack of specific protective antibody usually indicates susceptibility to that agent, although reactivation or reinfection to some agents may occur in the presence of antibody.

Transmission: The mechanism by which an infectious agent is spread to another host (see Section 5).

Virulence: A measure of the degree of pathogenicity of an infectious agent as reflected by the severity of the disease produced and its ability to invade the tissues of the host.

Zoonosis: An infection or infectious disease transmissible under natural conditions from animals to man. It may be *endemic* (enzootic) or *epidemic* (epizootic).

2.2. Methods

Epidemiology can be divided into descriptive, analytical, experimental, and serological epidemiology. The major analytic methods in use are the cohort (prospective) and case–control (retrospective). This section will briefly present these concepts. For more detailed descriptions, textbooks and recent articles of epidemiology are recommended.[18–21] A textbook on epidemiological methods that includes discussion and examples in infectious disease[18] is recommended before undertaking an epidemiological study. An excellent brief book on all aspects of epidemiological studies has been published by the World Health Organization (WHO).[22]

2.2.1. Types of Epidemiological Studies. Epidemiological studies may be descriptive or analytical. Descriptive studies are based on available data sources and describe the patterns of disease in population groups according to time, place, and person factors. Epidemic investigations begin with a descriptive study. These data often suggest clues to the etiology of the condition or to the risk factors involved. Analytical studies are then designed to test the hypotheses of causation developed from the descriptive studies and usually require new data to do so. Three common analytical methods are employed in pursuing epidemiological studies.

2.2.1.1. Cohort Study. This is the most definitive and expensive type of study and is based on identifying a group or groups of persons (cohorts) who are followed over time for the development of disease (or infection) in the presence or absence of suspected risk factors that are measured at the start of the study. These studies are usually carried out by identifying a cohort or usually two or more cohorts at the present time and then following them longitudinally over time. One cohort will be the group exposed to a risk factor or there may be several cohorts, each with a different degree of exposure. There usually is another cohort of unexposed persons who are followed in the same way. The cohorts are followed until the effect of the exposure occurs or the study is terminated for other reasons. If the occurrence of disease is the expected outcome, persons immune to the disease at the beginning of the study would not be included in a study cohort. This has been called a *prospective cohort study* or simply a *prospective study*. In infectious disease epidemiology, it may be possible to identify the persons in the cohort who are susceptible or immune at the start of the study by measuring the presence or absence of antibody in the initial serum specimens. Serial serum samples are then taken in which the appearance of antibody indicates the approximate time at which infection occurs. The occurrence of clinical disease at the same time provides information of the clinical–subclinical ratio. If the appropriate serum samples are taken and frozen, the actual testing can be delayed to the end of the study.

An alternative method of conducting a cohort study is to identify a group of persons at some time in the past who were presumably free of the disease under investigation at that time, as indicated by examining existing records. The cohort is then followed to the present, or even beyond, by measuring the occurrence of infection (by serological tests) or disease in that defined population. This approach is called a *historical cohort study* or a *retrospective cohort study*. Because the case–control study is also retrospective in terms of the time when the observations are made, it must be distinguished from the historical cohort study.

In a cohort study the statistical methods involve the calculation of the relative risk of the prevalence in the ill individuals as compared with the controls. This can be calculated using the format of a fourfold matrix as depicted in Table 1.

Table 1. Matrix for Calculating Relative Risk Ratios

	Number of persons		
Characteristic or factor	With disease	Without disease	Total
Present	a	b	$a + b$
Absent	c	d	$c + d$
Total	$A + c$	$b + d$	

If the frequency, $ala + b$, of the characteristic in persons with the disease (a) in this total group ($a + b$) is statistically significantly greater than the frequency of the characteristic in those without the disease ($c/c + d$), then an association may exist between the characteristic and the disease. For further details of the mathematical and epidemiological techniques and the biases involved in the selection of cases and controls, readers are referred to recent texts such as *Methods in Observational Epidemiology*.[18]

2.2.1.2. Case–Control Study. This has been called a retrospective study because it studies persons already ill with the disease and compares their characteristics with a control group without the disease for the presence or absence of certain possible risk factors. When a significant difference in the prevalence of a characteristic or risk factor is found, then the possibility of a causal association is suspected. Further studies using the cohort method are then often carried out to add strength to the association. The case–control study is usually the first type made because it is based on existing data, can be completed in a relatively short time, and is the least expensive. However, it cannot define the true incidence of the disease in relation to the various factors because the denominator at risk is not known.

A variation of the case–control study, and one encompassing the concept of a cohort study, is termed the *nested case–control study*. In this a large cohort is studied either prospectively or retrospectively for the occurrence of a specific disease, then these cases are matched by age and sex with persons in the original cohort who did not develop the disease. Various attributes of the two groups defined at the start of the study can then be compared. This method is very useful for diseases or conditions of low frequency in which analysis of the entire cohort would be an overwhelming task. An example of this is a recent study of Hodgkin's disease in relation to elevated levels of antibody to Epstein–Barr virus (EBV).[23] In this analysis, 240,000 persons whose sera had been collected and stored in four serum banks were followed for 5 years through cancer registries or hospital records for the development of Hodgkin's disease. Forty-three cases were identified in this manner and the EBV and other antibody levels were determined in sera from the group and compared with results from matched controls bled at the same time. A significant increase in certain EBV antibodies over those of controls was found 3–5 years preceding the diagnosis of Hodgkin's disease.

Biases may occur in case–control studies in the selection of cases, in the selection of controls, and in the elucidation of data by interview or records concerning the characteristics in question in both cases and controls. The selection of cases should ensure that they are representative of all patients with that disease. Ideally, this would assume that all patients with the disease seek medical attention, that the correct diagnosis is made and substantiated, that all medical facilities are canvassed, and that all cases are detected. In practice, these criteria are seldom met, and patients, for example, from a single hospital may be the only ones studied. This introduces a bias, since certain patients may be excluded from a given hospital because of such factors as age (e.g., no pediatric wards), socioeconomic level, or military or civilian status; the patient or physician may select a given hospital because of nearness, religious affiliation, the physician's privileges, nature of payment, or other considerations. These patients are not representative of all patients with the disease. The presence or absence of the characteristic under study may also influence the selection process for either the case or the control group or both, giving spurious associations.

Biases also are common in the selection of controls. Usually, controls should be selected from the same population group from which the patients are drawn and should be closely comparable to the cases in all known characteristics (age, sex, socioeconomic level, ethnic groups) except the one under study. Random selection from a large group may equalize those differences, but usually groups matched for certain variables or individuals matched carefully for paired comparisons are selected. However, if the two groups are matched too closely, the association between the cause and its effect may be masked. In a hospital setting, ill patients with diseases other than those under study are sometimes chosen. Bias may occur if some of these patients have diseases that are influenced by the characteristic in question. To limit this, patients with noninfectious diseases are often chosen in an infectious disease study. In a community setting, healthy controls may be advantageous. In matching, only those variables known to affect the disease should be selected. Each matching factor included, while controlling the results, eliminates the possibility of evaluating that factor itself.

To avoid bias regarding the presence or absence of a characteristic in the procurement of data by interview or from records, those charged with data collection should not know which is case or control, and the ascertainment should be uniform or standard. Once the data have been obtained, the odds ratio associated with a given characteristic is calculated from Table 1 by the cross-product of $a \times d$ divided by $b \times c$. This estimate is based on the assumption that the frequency of the disease in the population is relatively small and that cases and controls are representative of their respective ill and non-ill populations for that disease. Examples of case–control studies for an infectious disease would include the influence of some characteristic such as genetic makeup (HLA type), smoking, preexisting disease, or socioeconomic level as a

risk factor in a given disease. It should be emphasized that a particular risk factor might operate at different levels or at several levels: It might affect exposure and infection, the severity of illness after infection has occurred, the duration of disease, the development of complications, or the case-fatality rate.

The advantages of case–control studies as compared with cohort studies (see Table 2) include the relatively small numbers of subjects needed, their relatively high efficiency, the shorter time to complete the study, and their suitability for diseases of low incidence. Their disadvantages include difficulty in finding the needed information about the characteristic in question, or the inaccuracy of the information; bias in obtaining data; and bias in the selection of cases and controls. The appropriate selection of the control groups is probably the most difficult task.

2.2.1.3. Cross-Sectional or Prevalence Study. This third type of investigation examines the occurrence of disease and of suspected risk factors in population groups at a point in time or over a relatively short period of time. Prevalence rates among those with and without the exposure are determined and compared. This approach is usually limited to diseases of slow onset and long duration for which medical care is often not sought until the disease has progressed to a relatively advanced stage. Thus, the risk factors present at the start of the disease may be difficult to identify. This method is used for certain chronic diseases, such as osteoarthritis, chronic bronchitis, and some mental disorders,[24] but it may also be useful in certain infectious diseases such as those occurring in a hospital setting.

The reader should review more detailed descriptions of epidemiological methods such as found in Refs. 18–22 before undertaking any type of epidemiological study, as well as consult with a statistician in the planning stage to ensure the validity of the procedures and the adequacy of the number of subjects involved. See Section 5 for discussion of methods in epidemic investigation.

2.2.2. Experimental Epidemiology. In infectious diseases, this represents planned experiments designed to control the influence of extraneous factors, among those exposed or not exposed to an etiologic factor, preventive measure, or environmental manipulation by the investigator. One example is the planned introduction of an infectious agent in a controlled fashion into a group of animals or volunteers and the analysis of the spread of infection and disease within these groups as compared to a non-exposed group. Such studies offer the most scientifically controlled method of epidemiological study. Unfortunately, many bacterial species or agents may not induce infection or disease in animal models. Certain susceptible animals (marmosets, chimpanzees) may not be available for study or are too expensive. Volunteers are very difficult to utilize in today's

Table 2. Some Features of Cohort and Case–Control Studies

Features	Cohort	Case–control
Approach	Identify the subsequent incidence of disease in persons with or without given characteristic(s)	Identify the presence or absence of characteristic(s) in persons with or without a given disease
Starting point	Persons with or without certain characteristics	Ill persons and controls (healthy or with other disease)
Measurement	Incidence of infection or disease or both	Prevalence of characteristic
Type of observation	Serial, longitudinal surveillance of entire group for development of infection or disease or both	Single analysis by interview, records, or a laboratory test of the characteristic in persons with and without disease
Advantages and disadvantages		
Incidence	Can be measured directly	Not measurable directly
Risk	Direct assessment	Indirect assessment
Disease spectrum	Can be measured from infection to mild and severe disease in relation to characteristic(s) and to other diseases	Not measurable; a clinical case is the starting point
Factor(s) or characteristic(s)	Defined before disease develops	Factor(s) defined after disease develops
Bias	Little, usually, since information is recorded before the outcome is known, but problems in ascertainment, diagnosis, and follow-up may create bias	Bias may be present in interviewer, in patient, and in control; data from records may be incomplete
Attrition	Individuals may be lost to observation or refuse to be studied	Cases and controls may die prior to completion of study
Time	Often long period of observation	Can be short
Efficiency	Low except for diseases of high incidence	Comparatively high
Sample size	Large, depending on incidence of the infection or disease	Relatively small

ethical, legal, and social environment, and there are good reasons for these restrictions.

2.2.3. Serological Epidemiology. The systematic testing of blood samples from a defined sample of a target population for the presence of antibodies, antigens, genetic markers, specific cell-mediated immunity, and other biological characteristics is called a *serological* or *immunological survey*. It constitutes an important epidemiological tool. Serological techniques can (1) identify the past and current prevalence of an infectious agent in a community; (2) identify the incidence of infection by seroconversion or a rise in titer in samples obtained at two different times; (3) reveal the ratio of subclinical to clinical infections, when combined with clinical data; and (4) determine the need for immunization programs and evaluate their effectiveness as to the presence, level, and quality of antibody produced, its duration, and the degree of protection against disease. Serological techniques are useful in defining the incidence, clinical importance, and spectrum of illness of a new agent such as *Legionella pneumophila*. The presence of antibody or antitoxin to diphtheria, pertussis, and tetanus, as determined in a serological study, is a good reflection of the level of immunization and public health practice in a community. This is especially true of tetanus, since antitoxin is acquired almost solely through immunization and rarely, if at all, through natural infection. The use of serological surveys in areas where medical care, diagnostic facilities, and reporting practices are inadequate may provide information essential for the control and evaluation of immunization programs. The uses, advantages, and disadvantages of serological surveillance and seroepidemiology for viral infections are presented in Chapter 2 of the companion book[5] to this volume.

Seroepidemiology is more widely applicable to viral than to bacterial diseases because of the wider occurrence of demonstrable antibodies in viral than in bacterial infections and because of the better means to measure them. Nevertheless, these techniques have proved useful in variable degrees for brucellosis, cholera, diphtheria, legionellosis, leptospirosis, *Mycoplasma pneumoniae* infections, pertussis, Q fever, Rocky Mountain spotted fever, syphilis, tetanus, tularemia, and typhoid fever. Specific mention of their applicability will be found in the relevant chapters of this book. The development of monoclonal antibodies and diagnostic techniques, such as the enzyme-linked immunosorbent assay (ELISA) and the radioimmunoassay (RIA), permits highly specific, sensitive, and rapid serological diagnoses. Development of sensitive and simple DNA probes and the ability to amplify DNA by the polymerase chain reaction (PCR) provide tools not only for diagnostic microbiology but also for the identification of antigens in stored paraffin or frozen sections.[6]

3. Epidemics and Their Investigation

Detailed descriptions of the concepts and methods of epidemic investigation can be found in a number of articles and book chapters.[24–26] An excellent recent article discussing the use of the case–control method in epidemic investigation gives a thorough review of the subject and an extensive table of examples.[27] This section will only deal with the highlights of epidemic investigation.

3.1. Pathogenesis of an Outbreak

Three essential requirements for an outbreak of an infectious disease are (1) the presence or introduction of an infectious agent by an infected human, animal, bird, or arthropod vector, or its occurrence in air, water, food, soil, or other environmental source, or its presence in or on a fomite; (2) an adequate number of susceptibles; and (3) an effective means of transmission between the two. Five circumstances in which epidemics occur can be mentioned: first, when a new group of susceptibles is introduced into a setting where a disease is endemic; second, when a new source of infection is introduced into an area from which the microbial agent has been absent and many susceptibles are therefore present, as in the return of visitors from a foreign country, or the arrival of new immigrants, or the contamination of food, water, or other sources of exposure by an agent not normally present; third, when effective contact is made between a preexisting infection of low endemicity with susceptible persons as a result of changes in social, behavioral, sexual, or cultural practices. Crowding as in a prison camp or institution or exposure of a new portal of entry are examples. A fourth possibility is an increased susceptibility to infection or disease or both through immunosuppression or other factors that influence the host response, such as a preceding viral infection, nutritional disorder, treatment with immunosuppressive drugs, or presence of a chronic disease. The devastating effect of HIV on the immune system has resulted in a worldwide epidemic of enormous and increasing proportions. A fifth circumstance might be the increase in the virulence or dosage of a microbial agent. This may have accounted for the massive outbreak of waterborne *Cryptosporidium* infection that occurred in Milwaukee, Wisconsin, in March–April 1993, which involved 404,000 infected persons of whom 4,400 required hospitalization.[28]

Epidemics or outbreaks are often classified from the standpoint of the source of infection. A common-source or common-vehicle outbreak may result from exposure of a group of persons to a single source of infection. This could be an exposure to a common source occurring at a single point in time, as in most foodborne outbreaks (point

epidemics), and characterized by a sharply defined and limited epidemic curve, often within the incubation period of the disease. It could be exposure on a continued or extended basis, as would be the case from a contaminated water supply or air source (airborne) and would result in an extended epidemic curve. In the latter setting, variations in the epidemic curve could result from differences in the dosage and time of occurrence of the microbial contaminant in the common vehicle or in the amount consumed, or they could result from changes in the frequency of exposure of the persons at risk to infection. The secondary spread of certain infectious agents from human to human in a common-source outbreak will also alter the epidemic curve, often producing a group of scattered cases after the initial epidemic wave subsides; these are called *secondary cases* and can lead to *tertiary cases*.

A second type of epidemic spread called *propagated* or *progressive* is due to multiplication and spread of an agent from one host to another. This is also called *contact spread* and may be direct, indirect, or by droplets (see Section 7). This is most often human-to-human spread, but could involve animal or arthropod intermediates. Here, the epidemic curve depends on the number of susceptibles, the degree of contact with an infected host, the incubation period of the disease, the mechanism of transmission, the portal of entry, and the infectiousness of the causative agent. In either common-source or propagated outbreaks, the epidemic decreases or stops when (1) the number of susceptibles effectively exposed to the source is diminished by natural attrition, by immunization, by antibiotic prophylactics, or by actual development of the disease itself; (2) the source of infection is eliminated; or (3) the means of transmission is interrupted.

3.2. Investigation of an Outbreak

The general strategy in the investigation of an outbreak includes establishing whether an epidemic actually exists, determining its extent, identifying the circumstances under which it occurred (e.g., time, place, person), evaluating its probable mode of spread, and initiating the steps to be taken for its control. Notification to appropriate health authorities should be made and help in epidemic investigation sought, if needed, from appropriate national or state disease control agencies; written reports should be prepared and distributed. News releases should be prepared to inform but not unnecessarily alarm the public. The epidemiologist, clinician, and laboratory experts all have roles in the analysis and management of an epidemic. The specific steps in epidemic investigations are presented in Table 3.

Table 3. Steps in the Investigation of an Epidemic

1. Determine that an epidemic or outbreak actually exists by comparing with previous data on the disease
2. Establish an etiologic diagnosis if possible; if not, define the condition epidemiologically and clinically. Collect materials for isolation and serological test, and data from sick and well-exposed persons
3. Investigate the extent of the outbreak by a quick survey of hospitals, physicians, and other sources and its basic epidemiological characteristics in terms of time, place, person, probable method of spread, and the spectrum of clinical illness. Prepare a spot map of cases and an epidemic curve. Call in outside help if needed
4. Formulate a working hypothesis of the source and manner of spread as a basis for further study
5. Test the hypothesis by determining infection and illness rates in persons exposed or not exposed to putative source(s) of infection by questionnaire, interview, and laboratory tests. Try to isolate the agent from the putative source(s)
6. Extend epidemiological and laboratory studies to other possible cases or to persons exposed but not ill
7. Analyze the data and consider possible interpretations
8. On the basis of the analysis, initiate both short- and long-term control measures
9. Report the outbreak to appropriate public health officials
10. Inform physicians, other health officials, and the public of the nature of the outbreak and the ways to control it

3.2.1. Determination of the Presence of an Epidemic. An epidemic or outbreak is usually defined as a substantial increase in the number of cases of a disease in a given period of time for that particular geographic area; e.g., an increase in the number of deaths from influenza and pneumonia that exceeds by 2 standard deviations the average experience for that week over the past 5 years is said to indicate an influenza outbreak.

A clinical diagnosis confirmed by laboratory findings is most important in determining whether a specific disease has exceeded the number of previously recorded cases. Unfortunately, a laboratory-proved diagnosis may be difficult or impossible to establish, especially early in an epidemic.

A clinical and epidemiological definition including the key features of the disease may be needed as a guide to reporting and for disease recognition until the etiologic agent is identified and appropriate methods are developed for isolation of the agent and/or its serological identification. Recent examples of the use of this type of definition are Legionnaires' disease, toxic shock syndrome, and AIDS. Even when the causative agent is known and laboratory tools for diagnosis are available, the disease may not be reportable, thus making comparison with past experiences impossible. On a practical level, any apparent concentration in time or geographic area of an acute illness of marked severity or with unique clinical features involving the respiratory,

gastrointestinal, skin, or central nervous system deserves evaluation. In the absence of a specific diagnosis, a simple working definition of a case should be established on the basis of available clinical and epidemiological data. It should be concise and clear-cut. The number of such cases should then be determined by a quick telephone or record survey of hospitals, clinics, and appropriate practicing physicians in the area. If the epidemic seems to be widespread, as with influenza, a random telephone survey of homes may give an estimate of the attack rate. The rate of absenteeism from key industries and schools may also help define the magnitude of the outbreak.

3.2.2. Determination of the Circumstances Under Which the Outbreak Occurred. This often involves two phases: a preliminary assessment based on available data and a more intensive investigation when the situation is better defined.

3.2.2.1. Preliminary Assessment. This is usually based on existing clinical records. In addition to the key clinical features, the age, sex, race, occupation, home and work addresses, unusual behavioral or cultural characteristics, date of onset, recent travel, and functions attended by others in the group in the recent past should be recorded. A time graph is drawn of the epidemic cases by date (and maybe time) of onset, from which the incubation period may be estimable. The time from the onset of the first cases to the peak may give a clue to this, as will unique or single exposures to the presumed source of infection. A spot map (place) may reveal clustering of cases or a relationship to a common source in the environment (food, water, air, anthropod). The data are analyzed to identify the persons at highest risk or some common denominator of risk and to postulate the most likely means of transmission. Early identification of a common-source outbreak is most important for instituting control measures. This might be a single (point) exposure, as in a food outbreak, or a continued exposure, as in a contaminated water supply. Person-to-person spread, airborne transmission, arthropod-borne spread, and zoonotic disease, especially of domestic animals, should be considered.

Appropriate materials for laboratory investigation should be collected early in the outbreak, such as throat washings, stool specimens or rectal swabs, blood for culture, and an acute-phase serum sample. A public health or hospital laboratory should be consulted in this endeavor. Since antibody to an infectious agent may already be present in many persons already ill in an outbreak, it may be desirable for baseline antibody levels to collect serum from other unexposed persons or from those incubating the disease, such as other family members or neighbors. A higher geometric mean antibody titer to a specific agent in ill compared to unexposed persons implicates that agent in the epidemic. Appropriate samples from the environment (water, food) or from possible vectors (mosquitoes, lice) should also be collected for isolating the agent.

On the basis of this preliminary assessment, a hypothesis of transmission may be formulated and recommendations for immediate control and isolation techniques made. Surveillance plans for identifying added cases may be drawn up, the appropriate environmental data assembled (water, milk, food, air), and questionnaires prepared for cases and controls (if a case–control study is to be conducted) in a fashion permitting easy analysis (marginal punch cards, computer). Standardized forms for foodborne outbreaks are available from state health departments and the CDC.

3.2.2.2. Intensive Study. This analysis should confirm or negate the hypothesis. The questionnaires prepared for this phase should include all possible circumstances under which the epidemic occurred and be administered to those ill, those exposed but not ill, and a comparable group neither exposed nor ill. Sera and other materials should be collected from these groups for antigen and antibody tests. The completed questionnaires may then be analyzed for comparison of attack rates (illness rate) in the three groups and as related to various risk factors. Antibody analysis of sera taken at the time of the outbreak and of those taken 2–3 weeks later may not only confirm the diagnosis but also identify the occurrence of infection in persons who were exposed but did not become ill. It may be possible to identify the specific nature of an ongoing outbreak by comparing the geometric mean antibody titer of those patients who are acutely ill with that of other patients already convalescing or by comparing the titer of those not exposed with that of those who are ill. More intensive study of the environment, insect vectors, and animal reservoirs may be needed. The analysis should include hypotheses to find the one that best fits the available data.

On the basis of this appraisal, control measures, including immunization programs, and other preventive measures should be initiated. Irrespective of whether the causative agent can be identified or not, the key element is the interruption of the chain of transmission. A written analysis of the epidemic should be given to the appropriate authorities. If no causative agent can be identified, then the acute and convalescent sera and material for antigen identification should be frozen for later study when new etiologic agents or laboratory techniques are discovered. A good example of the benefit of this procedure is its use in retroactively identifying several outbreaks of Legionnaires' disease that had occurred prior to the outbreak in 1976 in Philadelphia, from which the organism was first isolated.[29]

3.3. Example of Investigating a Foodborne Outbreak

An outbreak of illness characterized by diarrhea, abdominal cramps, and little or no fever involved 366 college students on February 24, 1966, in a new dormitory complex at the University of Wisconsin.[30] A quick assessment indicated that illness was confined to students who ate in three of six dining halls that served food from a common kitchen to 3,000 students. No other dormitories were involved, and the cases were sharply limited in time. The epidemic curve shown in Figure 1 indicates a peak incubation of 14 h. Stool specimens were obtained both from ill and healthy students and from food handlers. Samples of leftover items of food were not available; however, refrigerated samples of routinely collected food items were found for testing. Food menus for the preceding evening revealed that the three dining halls in which ill students had eaten offered a choice of fish or roast beef with gravy, whereas the other three dining halls had a choice of hamburger or fish; the other food items were common to all six dining halls. On the basis of this preliminary assessment, the hypothesis was formulated that this was a foodborne outbreak due to an agent with an average incubation period of about 14 h (range 10–20 h) that was present in or introduced into one or more of the food items served exclusively in the three dining halls where students became ill. The laboratory was notified of this as a guide to its tests. For more intensive investigation, questionnaires concerning foods eaten, time of onset, and the clinical symptoms were distributed to both sick and well students who ate in the three dining halls. They were returned by 366 ill and 740 well students, representing all the ill and two thirds of the well students. The clinical data indicated that the illness lasted less than 24 h and was characterized mainly by diarrhea; about half the ill students complained of abdominal cramps. Nausea, vomiting, and fever were rare. The average incubation period was too long for a staphylococcal toxin, and the clinical features would be unusual for *Salmonella* or *Shigella*.

An analysis of food items is given in Table 4. The evidence incriminating a food is usually based on the greatest difference in percentage ill between those who ate and those who did not eat a given food. In this outbreak, 69.9% of those who ate beef with gravy became ill compared to 4.9% who did not eat this item who became ill; furthermore, no one who ate beef without gravy became

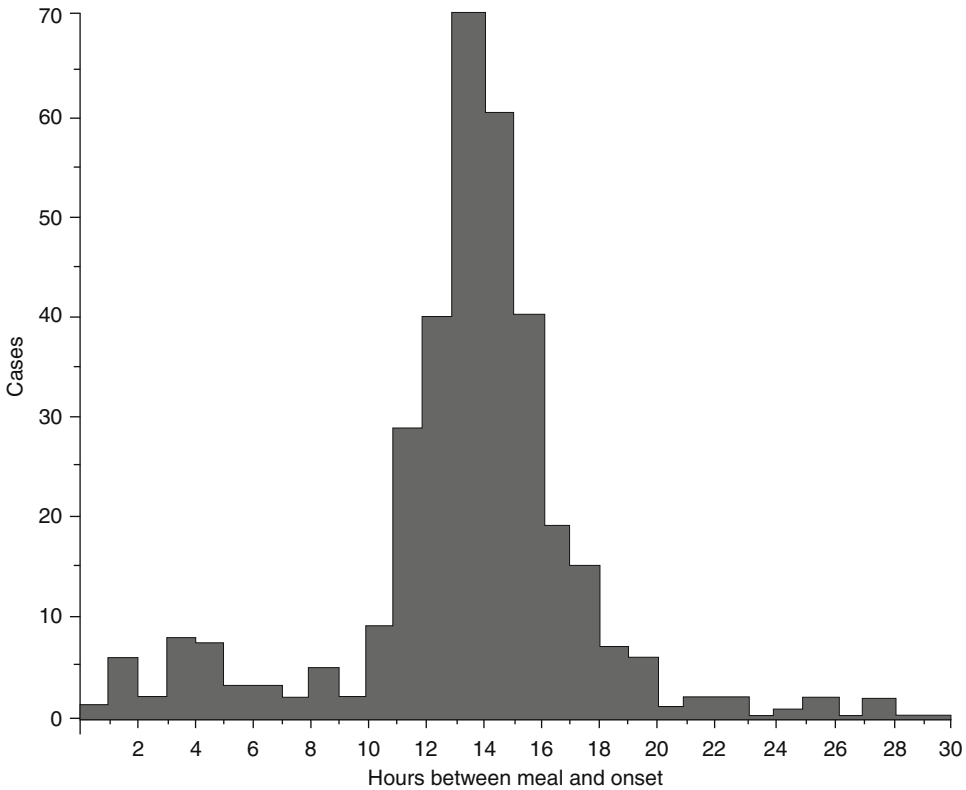

Figure 1. Epidemic curve of outbreak of *Clostridium perfringens* in a food outbreak involving 366 students at the University of Wisconsin. From Helstad et al.[30]

Table 4. Analysis of Attack Rate for Different Foods Eaten in a College Outbreak of Diarrhea[a]

	Ate food			Did not eat food			
		Ill			Ill		
Food item	Number	Number	Percent	Number	Number	Percent	Difference between ill and non-ill (percent)
Fish	391	16	4.1	715	340	47.6	–
Hamburger	188	15	8.0	918	351	38.2	–
Beef							
With gravy	479	335	69.9	627	31	4.9	65.0
Without gravy	48	0	0	1,058	366	34.6	–

[a]Derived from Helstad et al.[30]

ill, thus clearly incriminating the gravy as the likely source. The gravy as well as other foods available was negative on aerobic and anaerobic culture. Mouse-inoculation tests for toxin in the gravy were also negative; however, it was not known whether the gravy sample tested was from the incriminated meal or was set aside from a fresh gravy preparation. Laboratory analysis of fecal samples yielded the answer. Stool specimens from 19 of 20 ill students were positive for heat-resistant *Clostridium perfringens*, as was 1 of 24 stools from food handlers; no stools from 13 healthy students who had not eaten beef with gravy were positive. The organisms were isolated in thioglycollate broth after being heated 1 h in a boiling water bath. It was learned later that approximately 27 gal of bone beef stock had been kept overnight in the refrigerator in 9 gal plastic bags, mixed with 7 gal of fresh beef stock the next day, heated to a rolling boil, and served separately from the roast beef. Apparently, the inadequate heating of a heat-resistant preformed toxin in a very large volume of fluid had failed to destroy it. The control measures instituted were to prohibit future use of leftover gravy stock and to heat all items in smaller containers. *C. perfringens* food poisoning has an incubation period of 8–22 h with a peak of 10–14 h, closely fitting the outbreak described.

4. Agent

This book deals with microorganisms classified under "Lower protists (Prokaryotic): Bacteria." This grouping includes also the *Chlamydiae* (*Bedsoniae*) and the *Rickettsiae*, which are somewhat smaller than bacteria and are intracellular parasites.[31] Viruses, while classed as microorganisms, are sharply differentiated from all other cellular forms of life; they consist of a nucleic acid molecule, either DNA or RNA, that is enclosed in a protein coat or capsid. The principal groups of bacteria are presented in Table 5, which are derived from an "informal classification" presented by Jawetz et al.[31] in their excellent *Review of Medical Microbiology*, to which readers are to referred for discussions of microbiology, immunology, and host–parasite relationships. The new, beautifully illustrated book, *Medical Microbiology*, by Mims et al.[32] is also highly recommended.

The characteristics of microorganisms of epidemiological importance include those concerned with transmission through the environment, the development of infection, and the production of clinical disease. Table 6 summarizes some of these characteristics of bacteria, which include species pathogenic for humans.

4.1. Characteristics of Organisms That are Involved in Spread Through the Environment

For the spread of infection, a sufficient number of organisms must enter and survive transport through the environment to reach another susceptible host. Resistance to heat, UV light, drying, and chemical agents is important for survival of bacteria in nature. Some organisms such as *Vibrio cholerae* and *L. pneumophila* can survive for months in water, even in distilled water; others, such as *Bacillus anthracis*, attain survival through highly resistant spores. Organisms capable of actual multiplication within the environment in soil, plants, food products, milk, and elsewhere have an advantage for survival. The capacity to infect a nonhuman host such as animals or birds, or to be transferred through an insect vector such as the *Rickettsiae*, offers alternative pathways for the persistence and spread of microorganisms.

4.2. Characteristics of Organisms That are Involved in Production of Infection

Once bacteria have survived transport through the environment or intermediate host to reach a susceptible human host, several features of the bacteria are important in

Table 5. Key to Principle Groups of Bacteria Including Species Pathogenic for Humans[a]

Characteristics	Genera
I. Flexible, thin-walled cells with motility conferred by gliding mechanism (gliding bacteria)	
II. Same as I but with motility conferred by axial filament (spirochetes)	*Treponema, Borrelia, Leptospira*
III. Rigid, thick-walled cells, immotile or motility conferred by flagella	
Mycelial (actinomycetes)	*Mycobacterium, Actinomyces, Nocardia, Streptomyces*
Simple unicellular	
Obligate intracellular parasites	*Rickettsia, Coxiella, Chlamydia*
Free-living	
Gram-positive	
Cocci	*Streptococcus, Staphylococcus*
Nonsporulating rods	*Corynebacterium, Listeria, Erysipelothrix*
Sporulating rods	
Obligate aerobes	*Bacillus*
Obligate anaerobes	*Clostridium*
Gram-negative	
Cocci	*Neisseria*
Nonenteric rods	
Spiral forms	*Spirillum*
Straight rods	*Pasteurella, Brucella, Yersinia, Francisella, Haemophilus, Bordetella, Legionella*
Enteric rods	
Facultative anaerobes	*Escherichia* (and related coliforms), *Salmonella, Shigella, Klebsiella, Proteus, Vibrio*
Obligate aerobes	*Pseudomonas*
Obligate anaerobes	*Bacteroides*, Fusobacterium
IV. Lacking cell walls (mycoplasmas)	*Mycoplasma*

[a]Derived from Jawetz et al.[31]

the initiation and development of infection. One is the *infectiousness*, expressed as the ratio: number infected/number susceptible and exposed. A second is *pathogenicity*, a term used to denote the potential for an infectious organism to induce disease. It can be expressed quantitatively as follows: number with disease/number infected. The determinants of pathogenicity include mobile genetic elements such as plasmids, bacteriophages, and transposons.[33] The pathogenic process is complex and represents sequence of events in which many components are involved.[34] The adherence of organisms to host surfaces is a highly specific and essential step for subsequent events to develop. Epithelial surfaces provide appropriate sites for many bacteria. *M. pneumoniae* and *Haemophilus influenzae* find attachment sites in the respiratory epithelium, *Neisseria gonorrhea* in the urethral epithelium, and many enteric organisms (*V. cholerae, E. coli, Salmonella typhosa, Shigella flexneri*) in intestinal or colonic epithelium. Pathogenic organisms must possess characteristics that protect them against such host defenses as mucus and phagocytic cells. These protective features of the bacteria themselves include polysaccharide capsules (pneumococci, *Klebsiella, Haemophilus*), hyaluronic acid capsules and M proteins (β-hemolytic streptococci), and a surface polypeptide (*B. anthracis*). Toxins and certain extracellular enzymes may be important in the establishment of infection and in spread through tissues. The latter include collagenase (*C. perfringens*), coagulase (staphylococci), hyaluronidases (staphylococci, streptococci, clostridia, pneumococci), strepto-kinase or fibrinolysin (hemolytic streptococci), hemolysins and leukocydins (streptococci, staphylococci, clostridia, gram-negative rods), and proteases (*Neisseria*, streptococci) that can hydrolyze immunoglobulins, such as secretory IgA.[34] These surface properties and enzyme production contribute to the invasiveness of an organism.

4.3. Characteristics of Organisms That are Involved in Production of Disease

Disease is a rare consequence of infection. Usually, the presence of microorganisms on various surfaces of the body, their colonization on or in diverse epithelial cells, and their multiplication are unattended by signs of clinical disease.

Table 6. Bacterial Characteristics of Epidemiological Importance[a]

Epidemiological aspects	Bacterial characteristics
1. Features involved in *spread* through the environment	Number of organisms released by infected host
	Resistance to physical environment (e.g., heat, UV, moisture)
	Ability to multiply within environment
	Ability to infect intermediate host or insect vector
2. Features involved in initiation and development of *infection*	Host range of organisms
	Genetic makeup and antigenic diversity
	Infectivity of organism
	Pathogenicity of organism
	Number of organisms entering host and the portal of entry
	Enzymes involved in spread through tissues
3. Features involved in production of *clinical disease*	Most characteristics under (2)
	Virulence of organism
	Invasiveness of organism
	Production of endo- and exotoxins
	Immunopathologic potential

[a]Host attributes are considered in Table 7.

As with most viruses, infection without disease is a common outcome. However, since infection is a necessary basis for disease (excepting ingestion of preformed toxin), the attributes of organisms that are involved in infection are also important in clinical illness (see Section 4.2 and Table 6). The term *virulence* is used as a quantitative expression of the disease-producing potential of a pathogenic organism. Molecular studies of the determinants of virulence include how agents enter epithelial cells, a property that may be carried in different ways. In enteroenvasive *E. coli* it may be on a large plasmid, whereas for *Yersinia pseudotuberculosis* it is by a small DNA segment of the bacterial chromosome.[35] This property may be exchanged between bacteria, making noninvasive bacteria invasive.

Some organisms may lose apparent virulence if their structural identity is too close to the host's carbohydrates (for which the term *camouflage strategy* has been suggested). The factors that result in disease in an infected person are also determined by the host, as discussed in Section 6. Those that relate to the organism are invasiveness, the production of toxins, and the induction of an immune response that usually is beneficial but sometimes is detrimental to the host.

Invasiveness does not always correlate with disease and a widely disseminated organism does not always induce illness, but the wide distribution of a pathogen and its contact with many cells provide the potential amplification of any detrimental host response. That wide dissemination and a large number of organisms, even in the bloodstream, do not inevitably lead to toxemia is exemplified by the minimal host response evoked by large numbers of *Mycobacterium leprae* bacilli in the blood in lepromatous leprosy.

Organisms that produce endotoxins or exotoxins are likely to produce disease, since most are toxic to cells and evoke inflammatory responses. The exotoxins liberated by many gram-positive bacteria cause local cell and tissue injury; some damage phagocytic cells and thereby facilitate the spread of the organism. Examples include *Clostridium welchii, Clostridium botulinum, C. tetanus, Corynebacterium diphtheriae, S. dysenteriae, V. cholerae, B. anthracis, Bordetella pertussis, Streptococcus pyogenes*, and *Staphylococcus aureus*.[36] Some exotoxins are directly responsible for the characteristic clinical features of the disease, some are antiphagocytic, and some promote spread in tissues. They cause little or no fever in the host. Endotoxins are an integral part of the cell wall of gram-negative organisms. They are liberated in soluble form both during bacterial growth and presumably during death and disintegration of the organism. Endotoxins are strong immunologic adjuvants. They may produce fever in man and many other vertebrates; the pyrogenic action is mediated by a product synthesized by monocytes ("endogenous pyrogen") that acts on the thermoregulatory center in the hypothalamus. Other endogenous agents, such as prostaglandins and catecholamines, may also play a role. The lipopolysaccharide (LPS) is the most important component of endotoxin and is composed of a core polysaccharide common to many gram-negative bacteria, an O-specific polysaccharide conferring virulence and serological specificity, and a lipid A portion, mainly responsible for toxicity.[35] The effects of endotoxins appear to be mediated through leukotrienes, prostaglandins, and cachectin/TNF. Cachectin, which is identical to tumor necrosis factor,[37] is indistinguishable functionally from lymphotoxin, a product of activated T cells. This protein is produced by macrophages and by T cells in response to bacteria, viruses, and parasites and also occurs during cancers, resulting, in order of increasing dosage, in the following sequence of events: inflammation, cytotoxicity, cachexia, organ failure, irreversible shock, and death. There is a synergism between it and interleukin-1 in this phenomenon. Monoclonal antibody to cachectin/TNF can inhibit these responses and glucosteroids can also prevent endotoxin deaths. The gene for cachectin has been identified, and when put into hamster ovarian cells and then into nude mice results in cachexia. Despite these deleterious effects, cachectin/TNF in small doses appears to be beneficial in serving as a growth factor for macrophages

and as a tissue remodeler, a role for which it may have been designed in nature. It is not clear whether all these effects are mediated directly by cachectin/TNF or through mediators released by them. With large doses of endotoxins, there is also an effect that produces vascular collapse and death. Unlike exotoxins, endotoxins are heat-stable and are not fully convertible to protective toxoids. Endotoxins are normally released by many gram-negative bacteria in the intestines of healthy individuals, presumably absorbed in small amounts, and degraded by the Kuppfer cells. This occurs without pathological consequences on a continual basis and has a beneficial effect in stimulating the development of the immune system in the immature individual.[33]

Exotoxins are excreted by living cells, are quite unstable to heat, and consist of polypeptides of molecular weights from 10,000 to 900,000. They are highly antigenic and result in high titers of antitoxin that can neutralize the toxin. This antigenic property is useful in immunization with toxins rendered nontoxic by formalin, heat, and other methods. Different toxins produce disease via different mechanisms.[31] *C. diphtheriae* toxin results in inhibition of protein synthesis and necrosis of epithelium, heart muscle, kidney, and nerve tissues. The toxin of *C. tetani* reaches the central nervous system by retrograde axon transport where it increases reflex excitation in neurons of the spinal cord by blocking an inhibitor mediator. *C. botulinum* exerts its effect on the nervous system by blocking the release of acetylcholine at synapses and neuromuscular junction. Gut organisms, such as *Clostridium difficile*, produce a necrotizing toxin that leads to antibiotic-associated colitis, and that of *S. aureus* stimulates neural receptors from which impulses are transmitted to medullary centers controlling gut motility. *V. cholerae* toxin binds to ganglioside receptors on the villi of the small intestine, leading to a large increase in adenylate cyclase and AMP concentrations and the resulting massive hypersecretion of chloride and water and the impairment of absorption of sodium that characterizes the severe diarrhea and acidosis of cholera. Other toxins, such as that of hemolytic lysogenic streptococci, result in the punctate maculopapular rash of scarlet fever.

The production of clinical disease through immunopathologic mechanisms is more important for viral than for bacterial infections, but there are some examples of the latter. In streptococcal infections, antibodies may develop against an unknown component of the organism that is antigenically similar to heart muscle, leading to myocarditis. Immune complexes may also form, deposit in the kidney, and result in glomerulonephritis. In infections due to *M. pneumoniae*, the production of "heterophile" antibodies against human O erythrocytes (cold agglutinins) occasionally leads to acute hemolytic anemia. In primary infections by *M. tuberculosis*, the pathological picture is dominated by a vigorous and persistent cell-mediated immune response to the invading organism. The inflammatory, pathological, and immunologic processes of the host culminating in disease may be detrimental both to the host and to the microorganism. A successful parasite is one that leads to the least host response. For a more detailed discussion of microbial virulence factors, readers are referred to recent texts on infectious diseases and microbiology[32,38] and to recent articles.[34,39]

5. Environment

The external environment provides the setting in which the agent and host usually interact and is the usual means of transmission between the two. The effects of the environment on the organism itself are discussed in Section 4.1. The environment also contains the physical and biological mechanisms required for spread. The former includes air, water, and food and the latter animal, bird, and insect vectors. For some bacterial infections, the primary host is not man but some other living creature in the environment. This includes anthrax, brucellosis, leptospirosis, Lyme disease, Q fever, bubonic plague, Rocky Mountain spotted fever, salmonellosis, and tularemia. For infections involving insect transmission such as louse-borne typhus, Rocky Mountain spotted fever, and bubonic plague, the humidity, temperature, vegetation, and other factors in the environment may play a central role in limiting the occurrence of the infection to well-defined geographic areas favorable to the vector. Through climatic factors, the environment exerts an influence on exposure of the host to microorganisms. Warm weather and tropical climates result in recreational and occupational exposures to water, sewage, swimming pools, wild animals, and insects; they promote spread of skin infections in unclothed persons with abrasions on their skin. Certain organisms grow or survive better in warmer environments, especially enteric organisms. Intestinal infections flourish under such conditions. Inadequate refrigeration leads to foodborne outbreaks. Epidemics of Legionnaires' disease appear to depend on a chain of warm weather events. These include appropriate temperature and humidity for the organism to grow in soil or water, the contamination of a water-cooling tower or air conditioner, and airborne carriage or propulsion of the organism to susceptible humans, frequently in an enclosed environment (e.g., hotel, hospital, institution, club); July and August are good months for this.

The colder winter months, as well as school seasons in temperate climates of the northern hemisphere, bring individuals into close contact in a closed environment, facilitating spread of infections by the respiratory route. This includes bacterial infections of the central nervous system such as the meningococcus, *H. influenzae*, and pneumococcus organisms as well as true respiratory infections such as pertussis, bacterial and mycoplasmal pneumonias, tuberculosis, diphtheria, and streptococcal pharyngitis–tonsillitis. The peak period of different disease varies from one season to another. For example, pertussis and *M. pneumoniae* infections tend to occur most commonly in the fall and streptococcal infections in the spring. In addition, longer-term temporal trends in infection and disease occur within the same environment (as discussed in Chapter 2, Section 8.2). These changes reflect the complex interplay of agent, host, and environment. New strains of the organism, environmental alterations, varying behavioral patterns of the host, and the degree of immunization practice may change the pattern from one season to another.

The particular environmental setting—the macro- or microenvironment—also influences disease occurrence and its clinical patterns. In hospitals, certain types of skin, wound, and urinary infections are common, and their severity may be enhanced in persons who are already ill with another disease or are receiving immunosuppressive therapy. Antibiotic-resistant organisms are frequent in this setting. In prisons and in institutions for the mentally retarded or ill, low levels of personal hygiene and crowding contribute to the spread of respiratory, intestinal, and skin infections. Exposure in meatpacking and slaughterhouses or tanneries, or travel to developing countries, involves the risk of infection by various bacterial agents within that environment. With regard to children, the day-care center is posing an increasing hazard for them, as well as their parents for certain infectious diseases, especially respiratory and intestinal infections.[40] However, for young children infection is much more common than disease. For example, among 10,860 case contacts of an index case of *H. influenzae* type b infection in day-care centers, none of whom had received rifampin chemoprophylaxis, no clinical disease developed over an average 60-day observation period, although the carrier state was common.[41] Thus, rifampin prophylaxis of contacts may be unnecessary in these settings, although some other investigators disagree with this. For HIV infection, the environments of the brothel, the bar, and the bathhouse have provided ready transmission of this and other sexually transmitted infections, as has the "shooting gallery" of intravenous drug abusers. Travel to or residence in developing countries may result in exposure not only to specific tropical infections such as malaria, schistosomiasis, and cholera but also to many common respiratory and intestinal infections that the traveler might not encounter in a more hygienic setting. Even the homebody working in the garden or walking in the woods near home in endemic areas may be exposed to the bite of the deer tick or related species and become infected with *Borrelia burgdorferi*, the cause of Lyme disease.

6. Host

The occurrence of infection depends on exposure to a source of infection and on the susceptibility of the host. The development of disease in an infected person depends largely on factors intrinsic to the host, although some properties of the organism itself influence this. Some of the host factors are presented in Table 7.

They have been called the "clinical illness promotion factors."[3] Exposure to a pathogenic organism depends on characteristics of the human host that result in contact with sources of infection within the environment or that promote person-to-person spread. The behavioral pattern of the individual at different ages brings varying types of exposure in different seasons, cultures, and geographic areas. Personal habits such as intravenous drug usage or sexual promiscuity are also determinants of exposure. The family unit comprises an important setting for exposure and spread of infectious agents. The genetic background, nutritional habits, cultural and behavioral patterns, and level of hygiene within families create common patterns of exposure. The number and age of family members and the degree of crowding within the home also affect the transmissibility of infection. Hospitalization or institutionalization brings new exposures in closed environments. Heightened person-to-person contact and a mixture of susceptibles with infected or infectious individuals (carriers) underlie the increased risk of military recruits, children in day-care centers, and residents of institutions. Streptococcal, meningococcal, *M. pneumoniae, H. influenzae* type b, and enteric infections are common in such settings.

Occupational risks involve special types of exposures in certain occupations. The worker in the abattoir or slaughterhouse, meatpacking industry, or even at the butcher block is at risk to brucellosis, tularemia, and various parasitic infections. The sewage and sugarcane worker and the swine handler are exposed to leptospirosis, the tannery worker to anthrax, and the hunter to tularemia. The hospital worker is at increased risk to a variety of infectious agents, of which HIV is currently of greatest concern, although the risk is

Table 7. Host Factors that Influence Exposure, Infection, and Disease

Factors that influence exposure	
Behavioral factors related to age, drug usage, alcohol consumption	Military service
Familial exposure	Occupation
Hospitalization, especially intensive care	Recreation, sports, hobbies
Hygienic habits	Sexual activity: hetero- and homosexual, type and number of partners
Institutionalization: nurseries, day-care center, homes for the elderly and mentally retarded, prisons and other closed environments	Socioeconomic level
	Travel, especially to developing countries
Factors that influence infection, and occurrence and severity of disease	
Age at the time of infection	Entry portal of organism and presence of trauma at site of implantation
Alcoholism	
Anatomic defect	Genetic makeup, especially influences on the immune response
Antibiotic resistance	Immune state at time of infection
Antibiotic in tissues	Immunodeficiency: natural, drug-induced, or viral (HIV)
Coexisting diseases, especially chronic	Mechanism of disease production: inflammatory, immunopathologic, or toxic
Dosage: amount and virulence of organism to which person is exposed	
Double infection	Nutritional status
Duration of exposure to organism	Receptors for organism on cells needed for attachment or entry of organism

extremely small if universal hospital infection regulations are strictly followed. Hepatitis B infection is also of concern, and HBV vaccine should be given to all hospital staff exposed to blood or blood products.

Race does not usually influence infection if exposure is equal, but the response to infection may vary, such as the increased severity of tuberculosis in blacks. However, the separation of ethnic origin from other cultural, socioeconomic, behavioral, and genetic differences is often impossible. Recreational pursuits and hobbies influence exposures in both internal and external environments. The homemaker who prepares home preserves improperly may expose the ingestor to botulism; the home gardener or farmer is at risk to tetanus or Lyme disease, and the outdoorsman to various infections of wild animals. The influence of gender on occupational exposures has become of little importance, since women have entered almost all work areas including military life and many hazardous occupations. On the other hand, pregnancy is attended by special qualitative risks to infection, more commonly viral than bacterial, to which the male is not heir. Streptococcal B infections and syphilis are of special concern to the pregnant woman and her baby. Differences between the sexes in the portal of entry of microorganisms may result in different patterns of infection and disease, as is true in male homosexuals practicing passive rectal intercourse, in which the risk of infection with HIV is greatly increased. Genital lesions and discharges from sexually transmitted infections may also increase this risk in both sexes.

The socioeconomic level of the individual or the community affects the frequency, nature, and age at the time of infection. In developing countries and lower socioeconomic settings, infectious diseases, especially respiratory and enteric, constitute a leading cause of illness and death. The socioeconomic status influences infection and disease through a complex interaction of hygienic practices, environmental contamination, nutritional status, crowding, and exposure to animal and insect vectors.

Travel is an increasingly important risk factor because it may bring individuals into new settings, especially tropical or developing countries. Enteric infections are common hazards, especially toxogenic *E. coli, Campylobacter*, amebiasis, shigellosis, typhoid fever, salmonellosis, yersiniosis, and giardiasis. Enterotoxigenic *E. coli* (ETEC) is the most common cause and was found in 42% of diarrheal episodes in Latin America, 36% in Africa, and 25% in Asia. Other causes are various *Shigella* and *Salmonella* species. *Campylobacter jejuni, V. cholera, E. histoliticia, Giardia lamblia*, rotaviruses, and Norwalk-like viruses.[42] Mixed infections also occur. Bismuth subsalicylate had reduced the incidence of traveler's diarrhea by 65% in one study,[43] and its use is suggested for periods of up to 6 weeks.

Once infection has occurred, a number of factors influence whether clinical disease will develop and determine its severity (Table 7, part 2). Most of these factors are intrinsic to the host, although the dosage, virulence, and antibiotic resistance of the infecting organism play a role (see Section 4), as does the portal of entry. Entry sites that are close to vital organs or that permit easy access to invasion of the bloodstream may result in more severe and complicated infections. Among the host factors, age at the time of infection is an important determinant of the frequency of clinical illness

and its clinical features and severity. The presence of chronic diseases or other infections are risk factors. HIV infection greatly enhances the risk of opportunistic infections, of the reactivation of latent agents, and of malignancy.

Transmission of infection to the fetus in utero may result in fetal death or congenital abnormalities as with *Treponema pallidum*. Infections of the newborn such as those due to *Streptococcus B, C. botulinum*, and *Chlamydia trachomatis* may be severe and fatal. As is true in many viral infections, bacterial infections in childhood are often subclinical and less well localized than in the adult. The concept of "streptococcosis" illustrates this (see Chapter 34). In the newborn infant, respiratory involvement from group A infections is uncommon, although group B streptococci may cause sepsis and meningitis. In the age group 6 months to 3 years, group A infections have insidious development and mild symptoms. In the older infant and preschool child, a nonspecific streptococcal group A illness may be characterized by low-grade fever, irritability, and nasal discharge, sometimes accompanied by anorexia and vomiting. Clinical diagnosis is difficult. In the school-age child, upper respiratory infections due to group A predominate, and over half are manifested by the classic features of acute streptococcal pharyngotonsillitis: sore throat, often with tonsillar exudate, pharyngeal edema, dysphagia, enlargement of the anterior cervical nodes, and systemic symptoms (fever, chills, malaise). Another 20% may have milder and less localized illness, and 20% more may have either mild or no illness.

In general, the highest mortality from infection occurs very early in life, when immune defense mechanisms are immature, and in old age when they may be deteriorating. The clinical response to infection may also be more severe in conditions that alter or depress immune defenses. These include infection with HIV, organ transplantation, immunosuppressive drugs, and preexisting chronic disease, especially of the specific target organ of the infection; occurrence of a viral, parasitic, or other bacterial infection preceding or accompanying the current illness; and the prior use of alcohol or tobacco. The vigor and efficiency of the immune response may alter the host either favorably by control of the infection or unfavorably by certain immunopathologic processes. Genetic traits influence both susceptibility and disease. Their role in regulating the immune response is an important but often ill-defined one in relation to the occurrence and severity of the clinical disease. In tuberculosis, clinical illness among those infected has occurred more commonly in monozygotic twins and zygotic twins, even when other factors are controlled.[44] The nutritional level also affects host resistance. Malnutrition (especially severe protein deficiency) adversely affects phagocytosis and other primary defense mechanisms, the development of the thymus, and the efficacy of cell-mediated immunity against infections such as tuberculosis. In general, antibody formation is not impaired. The precise role of nutrition and vitamins in infection and disease is not well understood. Immunity is also influenced by vaccination, whether active or passive.

In summary, host factors may be divided into three major stages: (1) those that lead to exposure, (2) those that lead to infection among those effectively exposed, and (3) those that lead to clinical disease among those infected. The concepts of a clinical illness-promotion factor that leads to clinical illness[3] and of other, protective factors that result in subclinical or inapparent illness have been discussed.[4] Many of them remain unknown and they remain an important challenge to epidemiologists, microbiologists, immunologists, and geneticists.

7. Routes of Transmission

The major routes of transmission of bacterial infections are listed in Table 8 in general order of their importance. Many organisms have several routes. The sequence of spread usually involves the exit of the organism from the infected host; transport through the environment via air, water, food, insect, or animal, with or without bacterial multiplication; and the entry of a sufficient number of viable organisms into an appropriate portal of a susceptible host to initiate infection. For most infectious agents, specific receptors on the cell surface are needed to permit attachment and multiplication of the organism. Table 8 is loosely divided into human, animal–insect, and inanimate sources of infection in order to follow infection from its source to a human host, but the arrangement is sometimes artificial for those infections that exist primarily in other species or for those organisms that can multiply or survive in the natural environment.

7.1. Respiratory or Airborne

Organisms infecting the respiratory tract are either airborne via droplet nuclei or transmitted via droplets that are not considered true airborne transmission (see Section 7.2). The sources of the organisms carried by the air (droplet nuclei) include animate sources, the respiratory tract or oropharynx of infected persons, or from infected lesions of the skin, or from inanimate sources such as from water-cooling towers, as with *Legionella* organisms. Their success in reaching a susceptible host depends on the number of organisms present, the particle size, the force with which

Table 8. Transmission of Bacterial Infection[a]

Route of exit	Route of transmission	Examples	Factors	Route of entry
1. Human source				
1.1. Respiratory	Respiratory droplets or droplet nuclei	Bacterial pneumonias	Close contact or airborne	Respiratory
	RS and fomites	Diphtheria	Carriers	Respiratory, skin?
	Nasal discharges	Leprosy	Household contact	Skin, repiratory
	RS → droplets	Meningococcus	Crowding, military recruits, carriers	Respiratory
	RS → air, fomites	Pertussis	Direct contact	Respiratory
	RS → air	Plague (pneumonic)	Pneumonic case	Respiratory
	RS → droplets	Streptococcal	Close contact, carrier	Respiratory
	RS → droplet nuclei	Tuberculosis	Household contact	Respiratory
1.2. Skin squames	Respiratory, direct contact	Nosocomial bacterial infections	Hospitalization, surgery	Nose, respiratory, skin
	Direct contact	Impetigo due to staph and/or strep	Low socioeconomic level, tropics	Skin
	Close contact	Skin diphtheria	War wounds	Skin
		Yaws	Endemic foci	Skin
1.3. Gastrointestinal				
Enteric fevers	Stool → water	Cholera	Water, food, carrier	Mouth
	Stool → food	Salmonellosis	Food, animal contact	Mouth
	Stool → man	Shigellosis	Man to man only	Mouth
	Stool → water, food	Typhoid fever	Also food, flies	Mouth
Food poisoning	Food	Staph, *C. perfringens, Salmonella*, strep, *Vibrio parahemolyticus*	Inadequate refrigeration or cooking	
		Botulism	Home canning	Mouth
1.4. Urine	Water (swimming)	Leptospirosis	Infected animals	Skin
	Water	Typhoid fever	Poor sanitation	Oral
1.5. Genital	Sexual contact (hetero- or homosexual)	Chancroid	Mostly tropics	Urethra
		Chlamydia	Also carriers	Urethra, rectum
		Gonorrhea	Also carriers	Urethra, rectum
		Syphilis	Moist surfaces	Urethra, placenta
1.6. Placental	Congenital	Syphilis	Up to fourth month of pregnancy	Blood
1.7. Umbilical	Direct contact	Neonatal tetanus	Poor birth hygiene	Cord
2. Animal sources	Infected animal	Anthrax	Tanning	Skin, respiratory
		Tularemia	Skinning, dressing	Skin, eyes
	Bite of tick	Rocky Mountain spotted fever, Lyme disease	Outdoor exposure	Skin
	Rat flea	Bubonic plague	Infected rat	Skin
	Infected placenta via air	Q fever	Cows	Respiratory
3. Inanimate sources	Soil, air, water, food	Tetanus	Wound, childbirth	Skin
		Legionnaires' disease	Warmth, humidity, water coolers, air conditioners, potable water supplies	Respiratory

[a]This table is representative only and does not include all organisms. RS, respiratory secretions.

they are propelled into the environment, the resistance to drying, the temperature and humidity of the air, the presence of air currents, and the distance to the host. Some infections may be carried great distances from their sources, e.g., Q fever, tuberculosis, or Legionnaires' disease. As with viruses, respiratory-transmitted bacterial infections are difficult to control. The size of the particles in the aerosol influences its dispersion distance and the site in the respiratory passages at which the particles are trapped. Particles larger than approximately 5 μm in diameter are usually filtered out in the nose, while those up to 5 μm in diameter are deposited on sites along the upper and lower respiratory tract.

7.2. Contact

Contact transmission can be direct, indirect, or by droplets, which due to particle size are not truly airborne. Direct contact transmission means the agent is transmitted from an infected person or animal directly to a susceptible host; indirect contact transmission means the agent moves from the source to the susceptible host by means of an inanimate object. Droplets are infected particles more than 5 μm in diameter that only travel up to approximately 3 ft through the air before they infect a susceptible host or fall to a horizontal surface. Direct contact spread includes genital or sexually transmitted diseases, some gastrointestinal or fecal–oral spread diseases, and some other diseases such as tularemia resulting from contact with an infected animal.

Bacterial infections of the skin are transmitted usually person to person from an infected lesion or via squamae. They are commonly due to staphylococcus or streptococcus or a mixture of the two. They are manifested as boils, carbuncles, impetigo, and erysipelas. They are particularly common in warm and tropical climates and in settings of poor hygiene. Yaws, a nonvenereal, contagious disease of the skin and bones due to *Treponema pertenue*, is endemic in many tropical areas and is similarly transmitted; effective eradication programs with penicillin sponsored by the WHO have been carried out in many countries. Diphtheritic skin infections may also occur, especially in tropical climates, and may contaminate wounds.

7.3. Genital or Sexually Transmitted

The term *venereally transmitted* is now being limited to the five classic infections clearly transmitted by sexual intercourse (gonorrhea, syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale). The newer term, *sexually transmitted diseases* (STD), is broader, applies to both hetero- and homosexual activities, and encompasses all infections transmitted person to person during sexual activity. In recent years, *C. trachomatis* has been identified in this group as the cause of almost half of nongonorrheal urethritis (see Section 11.2.6 and Chapter 9), and *Ureaplasma* is under evaluation; enteric infections are of increasing importance in male homosexuals. The presence of ulcers due to STDs enhances the spread of HIV, especially a penile lesion from syphilis or herpes simplex.

7.4. Gastrointestinal or Fecal–Oral

The fecal–oral route of transmission is a close rival in frequency to respiratory spread and there are many sources of infection. A first group is called enteric fevers. Bacterial organisms from ill persons or carriers exit via the gastrointestinal tract to the external milieu for transmission via water, food, or direct contact to another individual. They constitute a major group of bacterial infections. The mouth is the common portal of entry. Some enteric infections involve only a human-to-human cycle, such as cholera, typhoid fever, and shigellosis. Others, such as salmonellosis, *Campylobacter* infections, and yersiniosis, also involve animal hosts. A variety of mechanisms may transmit the organism from the infectious stool to a susceptible person. Cholera is commonly transmitted by water, and on occasion by food (such as undercooked seafood like oysters and clams). Shigellosis is spread by the fecal route from patients or carriers and also by food, water, or flies. Typhoid fever is transmitted by food or water contaminated by the feces or urine from a patient or carrier and sometimes through contaminated shellfish or canned goods. *Salmonella* organisms are widely disseminated in nature and infect many domestic animals and birds, providing many potential sources of contamination of food and, less commonly, of water. *Campylobacter fetus* subsp. *jejuni* and *Yersinia enterocolitica* also infect many animals, including domestic ones such as puppies, and can infect exposed humans through direct contact or through water, milk, or food. For shigellosis, exposure to an infected human during the acute illness or shortly thereafter is the main source of infection; here, direct or indirect fecal–oral contact is usually more important than water or food. There is no extrahuman reservoir of infection.

A second group of gastrointestinal infections is called food poisoning. Here, contamination of food may occur from the feces of an infected person or carrier (food handler), but other sources of the organism are also common. The animal food source may be infected (i.e., *Salmonella* in chickens), or the organism may be present on the skin of the food handler (staphylococcus, streptococcus), in the environment (staphylococcus), in the soil (*C. perfringens, C. botulinum*), or in raw seafood (*Vibrio parahemolyticus*).

The transmission of enteric fevers and food poisoning is largely preventable. A good source of water, proper chlorination or boiling, frequent hand washing, appropriate refrigeration of foods, and thorough cooking are effective ways of interrupting the chain of infection. However, in developing countries and low socioeconomic settings, neither the means nor the education to carry them out may be available. Some may be prevented by immunization. Transmission of enteric infections by homosexual activity is a newly recognized and important problem in this group, and infection in HIV-infected patients may result not only from a wide variety of usual pathogens such as *E. coli* but also from organisms usually regarded as commensal and nonpathogenic such as the parasitic infection *Cryptosporidium*. However, this

organism caused a massive outbreak related to the public water supply of the city of Milwaukee in normal hosts.[28] This organism and other related ones are able to pass through usual water filters and are highly resistant to the usual levels of control. Increased surveillance of their occurrence in wells and public water systems is currently being carried out in several states under the auspices of the CDC.

7.5. Urinary

Urinary spread of infection is not common, but may occur in typhoid fever from an infected person and in leptospirosis from many animal hosts. Water is the common vehicle of transmission.

7.6. Perinatal

These infections occur at the time of childbirth. In *congenital infections*, the organism is transmitted *vertically* from an infected mother via the placenta to the fetus. Congenital syphilis, rubella, and toxoplasmosis are examples of this. Infections may occur *horizontally* from an infected cervix to the baby as it passes through the birth canal, as in gonococcal ophthalmia and chlamydial infections. Infections may also be acquired immediately after birth, as exemplified by tetanus neonatorum due to contamination of the newly cut umbilical cord by soil or a contaminated substance applied to the umbilical stump.

7.7. Insect Vectors

Rocky Mountain spotted fever is transmitted by the bite of the tick, which may remain infective for a long time, and the infection is maintained in nature by transovarian and transstadial passage. A mite has been implicated as the means of transmission of rickettsialpox from infected house mice. The transmission of bubonic (sylvatic) plague is through the rat flea (mostly *Xenopsylla cheopis*) from infected wild rodents. *B. burgdorferi*, the cause of Lyme disease, is transmitted by small Ixodes ticks, such as the deer tick, *Ixodes dammini*.

8. Pathogenesis

A section on pathogenesis is included in every chapter of this volume that deals with specific infections. Only a few concepts will be presented here. An excellent book by Mims,[35] entitled *The Pathogenesis of Infectious Diseases*, should be consulted for details, as well as more recent articles by him[36] and others.[33,34] Recent texts of medical microbiology[32] and infectious diseases[38] also contain excellent discussions.

8.1. Localized or Superficial Infections

Many bacterial infections produce diseases through the cells with which they first come in contact in skin or epithelial surfaces and remain limited to that area. Tissue damage results from the direct action of the bacteria, microbial toxins, indirect injury, inflammation, or immunopathologic processes. Most bacteria have specific attachment sites on epithelial surfaces (see Section 4.2). Examples of localized infections include diphtheria and streptococcal infections of the throat, gonococcal infections of the conjunctiva or urethra, cholera, and most *Salmonella* infections of the intestine. Many gram-negative bacteria have a limited capacity to invade tissues and tend to remain localized; some are able to invade only in debilitated, malnourished, or immunocompromised patients. Host antibacterial forces limit the spread of many bacteria. At the subepithelial level, three important defense mechanisms are called into play: (1) tissue fluids, (2) the lymphatic system leading to the lymph nodes, and (3) phagocytic cells (macrophages) in tissues and polymorphonuclear cells in the blood. Each of these mechanisms depends on the inflammatory response for its action,[35] as manifested by four cardinal signs: *warmth* and *redness* due to vasodilatation, *swelling* (vasodilatation and exudate), and *pain* (tissue distention, pain mediators). Polymorphonuclear cells enter, as well as macrophages and lymphocytes; exudation occurs. Tissue fluids provide plasma proteins, including immunoglobulins, such as IgG, complement, and properdin. The primary mediators of inflammation include histamine, 5-hydroxytryptamine, and kinins. Prostaglandins E and F are thought to play a role in the termination of the response. Microorganisms in peripheral lymphatics are rapidly carried to lymph nodes, where they are exposed to macrophages lining the sinus that act as a bacterial filter. Here, too, polymorphs, serum factors accumulating during inflammation, and the initiation of the immune response limit the infection. The phagocytic cells play a key role in the interaction with microorganisms, ingesting and killing bacterial invaders. Among the chemotractant factors for phagocytosis are platelet-activating factors, leukotriene B4, C5a, and certain formyl peptides.[33] The details are fully described by Mims,[32,36] as are the ways in which some bacteria are able to resist or interfere with phagocytic activity. Organisms that escape must still face one or two encounters with the macrophages, as well as other immune mechanisms, before successfully reaching the venous system.

8.2. Systemic Infections

Organisms that escape phagocytic cells and the other local defense mechanisms can spread through the tissues and, more distantly, via the lymphatics and the bloodstream. Some viruses (herpes, HIV, poxviruses, measles), some rickettsiae (*Rickettsia Rickettsii, R. prowazekii*), and some bacteria (*M. tuberculosis, M. leprae, Listeria monocytogenes, Brucella* spp., and *L. pneumophila*) actually multiply in macrophages. The toxins, enzymes, and surface components of bacteria that protect them against phagocytic destruction and promote invasiveness have been mentioned in Section 4. It is not clear what exact role the proteinases, collagenases, lipases, and nucleases produced by bacteria play in the pathogenesis of infection or which ones are related to nutritional and bacterial metabolism.

Lymphatic spread may occur from the lymph node, which serves not only as a focus of phagocytic and immune forces but also, if these fail, as a focus of dissemination. These results occur when the lymph flow rate is high from inflammation of tissues or from exercise of muscles, when the number of bacterial particles exceeds the filtration rate or the defense mechanisms of the node or both, and when phagocytic activity is impaired. In some instances, certain organisms such as *Pasteurella pestis* and brucellosis actually multiply in the lymph node and spread via efferent lymph channels. In other instances, vigorous inflammatory responses localize the infection, and the node becomes a graveyard of dead and damaged bacteria and of tissue cells.

Bloodstream or *hematogenous spread* is the most effective mechanism for the dissemination of an infection throughout the body. Bacteria may exist free in the plasma (pneumococci, *B. anthracis, Leptospira*), intracellularly in monocytes (*Listeria*, tubercle and leprosy bacilli, *Brucella*), or in association with polymorphonuclear cells (many pyogenic bacteria). The *bacteremia* may be transient and with little or no systemic response, as follows dental extraction in a healthy person; even a continuous bacteremia may exist with few toxic signs, as in leprosy where the organism exists in large numbers inside blood monocytes. On the other hand, severe systemic manifestations may accompany the presence of large numbers of organisms in the blood such as the pneumococcus, meningococcus, or group A *S. pyogenes*. This is called a *septicemia*. Bacteria may succeed in setting up foci of infection in areas where the blood flow is slow enough, or they may establish multiplication in sites previously damaged by disease or injury, such as *Streptococcus viridans* on abnormal heart valves producing subacute bacterial endocarditis, or staphylococci in the traumatized long bones of children may lead to osteomyelitis. Depending on the site of the infection, the liver and lung may receive many organisms during bacterial invasion of the bloodstream. The lung, liver, spleen, and bone marrow may also serve as important foci of dissemination of organisms, as in brucellosis, leptospirosis, and typhoid fever. Rashes accompany the dissemination of many viral and some bacterial infections to the skin. They may result from localization and growth of the organism in small blood vessels, producing thrombosis, infarction, and hemorrhage as in the rickettsial diseases, Rocky Mountain spotted fever, and typhus, as well as the petechial and purpuric lesions of meningococcemia. Immunopathologic processes involving sensitized lymphocytes, antibodies, and immune complexes play a role in many rashes, especially viral. A bacterial toxin may induce the rash as in scarlet fever. Some organisms such as *T. pallidum* in secondary syphilis extravasate from blood vessels and multiply in extravascular tissues. This results in highly infectious lesions that discharge to the exterior. Dissemination of *T. pallidum* to the blood–fetal junction in the placenta during pregnancy may result in infection of the fetus; slow blood flow in the placenta may contribute to this possibility.

Central nervous system (CNS) and meningeal involvement can occur by bloodstream carriage of the organism to the blood–cerebrospinal fluid junctions in the meninges or choroid plexus; from there, passive transport occurs into the flow of fluid from ventricles to subarachnoid spaces and throughout the CNS. Examples of bacteria that traverse this barrier and produce meningitis are the meningococcus, tubercle bacillus, *L. monocytogenes*, and *H. influenzae*. Actual spread along peripheral nerves has been shown for rabies and herpesviruses and is the means of centripetal passage of tetanus toxin.[45]

9. Incubation Period

The period of time from exposure to a source of infection to the first signs or symptoms of clinical illness is called the incubation period (IP). It varies with (1) the nature and dosage of the organism; (2) the portal of entry; (3) the type of the infection (localized or systemic); (4) the mechanism responsible for tissue injury (invasion, toxin, immunopathologic process); (5) the immune status of the host, being prolonged in the presence of partial immunity; and (6) other unknown factors individual to the host. The IP has many uses in epidemiology: (1) it helps define the etiologic agent in an epidemic; (2) it helps differentiate common source from propagated epidemics and identify the reservoir and/or source of the agent; (3) it delineates the period for which a person exposed to an infection is at risk to development of disease; (4) it assists in identifying the period of

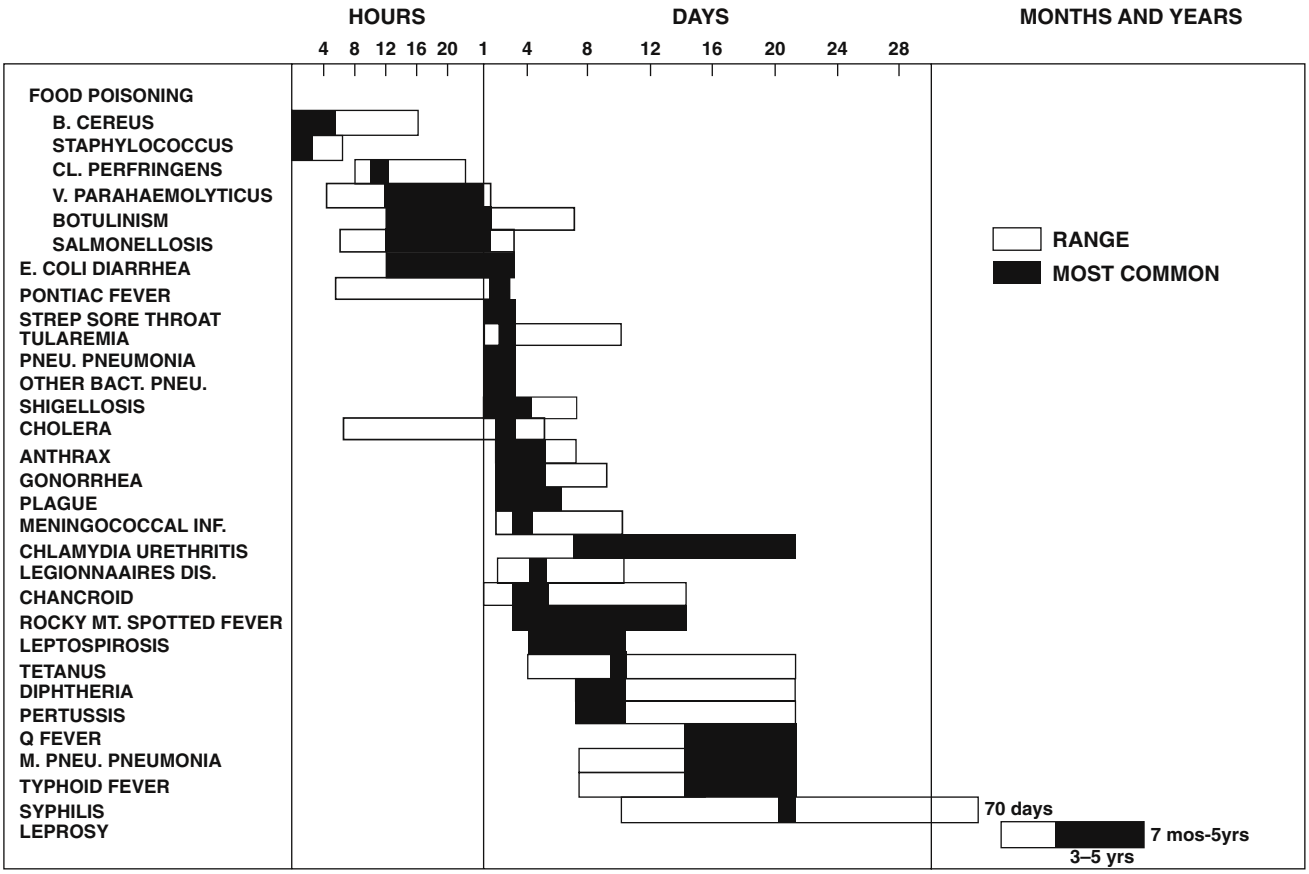

Figure 2. Incubation periods of common bacterial diseases. Derived from *Control of Communicable Diseases in Man*.[17]

infectiousness; (5) it provides a guide to the possible effectiveness of active or passive immunization; and (6) it gives clues to the pathogenesis of the disease.

The IPs of common bacterial diseases are given in Figure 2. Signs and symptoms due to preformed toxins or associated with food poisoning usually occur within 36 h after ingestion, sometimes as soon as 2–4 h, as in diarrhea due to *Bacillus cereus* or staphylococcal contamination of food. Traveler's diarrhea due to toxigenic *E. coli* has an IP of 12–72 h. Pontiac fever, the term used to describe an acute febrile disease without pneumonia recognized first in the Pontiac, Michigan, health department clinic and due to *L. pneumophila*, has a peak IP of 36 h, as compared to a peak IP of 5 days for Legionnaires' disease (pneumonia). It is not known whether this difference is due to a larger number of organisms inhaled in Pontiac fever (unlikely because of the comparative mildness of the disease), to dead organisms, or to some other factor.

Diseases due to direct involvement of epithelial surfaces have relatively short IPs, often under a week, such as streptococcal sore throat, bacterial pneumonias, shigellosis, cholera, gonorrhea, and chancroid. This is not invariably true, since diphtheria and pertussis both tend to have an IP of over a week, sometimes up to 3 weeks, and *M. pneumoniae* pneumonia has an IP of 2–3 weeks. These organisms may be less pathogenic. Diseases with longer incubation periods in the range of 2–3 weeks include systemic infections such as typhoid fever and brucellosis. The IP of syphilis most commonly is 3 weeks, although it may be as short as 10 days. Leprosy has an extremely long IP of 7 months to over 5 years.

10. Immune Response

A concomitant requirement for the evolution of multicellular life-forms was the development of methods for assuring the integrity of self. In the absence of the ability to recognize and cull out foreign cells, multicellularity could not have succeeded as a strategy. The mammalian immune

system is probably the most sophisticated antimicrobial defense in nature and represents the culmination of a billion-plus years of evolutionary refinement to the methodology of discriminating self from nonself.

Defense against microorganisms takes place at several levels in mammals. The term *innate immunity* refers to various features of an animal that confer natural resistance to invasion by microbes. These include physical barriers such as the skin and mucous membranes, chemical barriers (e.g., skin pH, lysozyme in saliva and tears), and the symbiotic bacterial flora of an animal that discourage colonization by pathogenic microbes.

Nonspecific immunity involves those processes in the immune response that do not react to specific individual foreign bodies and materials (antigens), but react to all foreign antigens with more or less equal vigor. The nonspecific immune system includes phagocytic cells, such as macrophages and polymorphonuclear neutrophils, the complement system, natural killer cells, cytokines such as the interferons and tumor necrosis factors, eosinophils, and basophils.

The third component of mammalian immunity is *antigen-specific immunity* or *adaptive immunity*. It is this component that appears to be unique among the vertebrates. Orchestrated by the lymphocytes, antigen-specific immunity recognizes foreign antigen in a highly specific fashion, expanding and activating only that subset of lymphocytes that can directly recognize and engage that precise antigen and no other. One of the most remarkable features of the antigen-specific immune system is the breadth of its capacity: The mature human immune system has been estimated to have the ability to respond discreetly to as many as a billion different antigens.

What follows is a very cursory overview of the components of the human immune system. For readers interested in more in-depth coverage, consult the general textbooks by Paul[46] or Kuby.[47]

10.1. Nonspecific Immunity

Nonspecific immunity plays numerous critical roles in the immune system. Many of the cells involved in nonspecific immunity participate in inflammatory responses and include macrophages, neutrophils, eosinophils, basophils, and mast cells. Overt tissue injury, whether caused by physical insult or invasion by a pathogen, stimulates the release of chemotactic factors that promote the migration and accumulation of various inflammatory cells at the damage site. Macrophages and neutrophils, particularly when activated by T-cell cytokines such as interferon-γ (IFN-γ), interleukin-4 (IL-4), and granulocyte-monocyte colony-stimulating factor (GM-CSF), are aggressively phagocytic cells. In the earliest phases of an infection, these cells serve to destroy bacteria and viruses and to mop up any debris, such as dead cells. Eosinophils are poorly phagocytic but are prominent in parasitic lesions, where they may be triggered to release a potent cocktail of enzymes and chemicals that destroy infecting parasites. Basophils and mast cells also have roles in immunity to parasites, but more as facilitators for the accumulation of other cells into a lesion.

Complement is a conglomeration of interacting proteins present in the bloodstreams of all vertebrates that have several important roles in nonspecific immunity. Various components of activated complement can promote and regulate inflammation, enhance phagocytosis through improved binding between the phagocyte and its target, and directly mediate cytotoxicity against cells and microbes. Several cleavage products of the complement activation cascade (C3a, C5a) have chemotactic and vasodilatory activity. A cleavage product of complement component C3, termed C3b, binds to specific receptors on macrophages and has lectin-like binding affinity for many bacteria, thus promoting opsonization. Complement activation culminates with the production of cannulus-like pores that self-insert into cell membranes (including those of bacteria), leading to colloid osmotic lysis.

Natural killer (NK) cells are a population of large granular lymphocytes that lack a receptor for specific antigen. They have a role in the immune surveillance of tumor cells and are capable of destroying their target cells by inducing apoptosis or programmed cell death.

Nonspecific immunity often serves to delay the progression of infection until the adaptive arms of the immune system have time to respond more specifically and effectively. Nonspecific immune mechanism is also frequently enhanced through the formation of partnerships with components of adaptive immunity. For example, specific antibodies may bind through specialized receptors to the surface of phagocytic cells, thus conferring antigen specificity to cells that otherwise have none. Cytokines secreted through the antigen-driven activation of T cells may enhance the level of activity of phagocytic cells or direct them to migrate to the site where they are needed. The activity of NK cells may also be enhanced by T-cell cytokines, particularly IL-2.

10.2. Humoral Immunity

There are two compartments of the immune system that are capable of responding specifically to foreign antigens. Humoral immunity, mediated by antibody molecules, is generated by B lymphocytes. Mature B lymphocytes bear specific receptors for antigen on their surface; the receptor on each circulating naive B lymphocyte is different from that

of all others, and each lymphocyte has one and only one specificity for an antigen. The receptor on the B lymphocyte is the immunoglobulin, or antibody, molecule itself, and upon activation, copies of this antibody are actively secreted. Since only those B lymphocytes that bind specifically with the antigens of a given bacterium or virus will be activated, the population of secreted antibodies that results is also specific for the invading pathogen.

With one limited exception, B-cell activation is absolutely dependent on the participation of T lymphocytes, which provide helper activity in the form of cytokines. T-cell cytokines are required for the activation of the B cell, for its differentiation into a plasma cell (the antibody-secreting cell), and for its proliferation (required to maximize the production of specific antibody). T-cell-derived cytokines also direct the class of antibody molecule that a B cell will ultimately produce.

Five distinct classes or *isotypes* of antibody molecules are found in the mammalian immune system, each of which has distinct roles in antimicrobial defense:

1. *IgM* has at least two important roles in humoral immunity. In monomeric form, it is expressed on the surface of all mature, naive B lymphocytes and serves as the receptor for antigen on those cells. In the circulation, IgM occurs as a pentamer, with five identical subunit antibodies bound together by a protein called J chain. IgM is the predominant antibody produced during the first exposure to an antigen. In serum, pentameric IgM has the highest binding avidity of any of the isotypes of immunoglobulin. It is extremely efficient at agglutinating bacteria and is an excellent opsonin, promoting phagocytosis by macrophages and neutrophils. In addition, IgM is the most effective antibody at activating complement.
2. *IgG* is the most abundant immunoglobulin in serum, making up 75% of the total serum antibody. It is the predominant antibody produced in a secondary or anamnestic immune response. Four distinct subclasses of IgG are recognized. All four subclasses of IgG can activate the complement cascade, although with widely different efficiencies. In addition, specific receptors for the constant region of all four IgG subclasses have been identified on a variety of cell types, including macrophages, mast cells, neutrophils, and lymphocytes. The combination of antibody with these other cell types either confers opsonic capacity or leads (in the presence of specific antigen) to the release of mediators. On lymphocytes, the binding of immunoglobulin molecules to such receptors appears to have regulatory functions, such as switching off the secretion of antibody. IgG is the only immunoglobulin that is capable of crossing the placenta, a process that is mediated by a specific receptor for IgG located on placental cells. In addition to its other activities, IgG is the most important neutralizing antibody in the serum, by virtue of its relative abundance.
3. *IgA* is the principal antibody found in local secretions. IgA antibody can be found in tears, saliva, milk, sweat, lungs, nasal passages, the urogenital tract, and the gut. IgA plays a crucial role in the defense of mucosal surfaces, neutralizing bacteria and viruses at local mucosa before they have an opportunity to invade. The presence of large quantities of IgA antibody in milk and colostrum enables the efficient transfer of maternal humoral immunity to newborn infants. IgA is incapable of fixing complement. It serves primarily as an agglutinating and neutralizing antibody.

   IgA in local secretions occurs as a dimer, bound by J chain. IgA transport to local mucosa is mediated by a molecule called the secretory piece, produced by cells adjacent to mucosal sites. IgA associates with the secretory piece on the cell surface and is endocytosed, transported across the cytoplasm, and deposited at local mucosa.
4. *IgE* makes up less than 0.01% of the total serum antibody. IgE is best recognized for its role in mediating immediate-type hypersensitivity, caused by the degranulation of mast cells and basophils in various mucosal tissues. IgE has an important role in the response against parasites. The purpose of the release of vasoactive substances when IgE bound to the surface of a mast cell or basophil encounters antigen is to enhance the accessibility of neutrophils and eosinophils, serum IgG, and complement to the site of parasitic infection.
5. *IgD* has no direct role in mediating defense against infectious diseases. It is present, together with monomeric IgM, on the surface of all naive B lymphocytes and appears to have a role in primary B lymphocyte activation.

10.3. Cell-Mediated Immunity

The second compartment of antigen-specific immunity is cell-mediated immunity (CMI). It is mediated by T lymphocytes. T cells are superficially indistinguishable from B cells. The T-cell receptor for antigen is structurally similar to the B-cell receptor, and yet the two cell types recognize specific antigen in fundamentally different ways. B cells recognize intact antigen and respond with the production of molecules that bear an exact copy of the surface receptor's binding site. T cells have no capacity for recognizing intact antigen. To engage a T-cell receptor, antigen first must be processed into small peptides, which are then inserted into the binding cleft of a major histo-compatibility (MHC) antigen. The MHC antigens are a highly polymorphic family of dual polypeptide proteins, at least some of which are expressed on nearly every cell type in the body. Because there are at least several hundred allelic variants of MHC antigens, and because no human being can express more than 12 different variants (up to two each of six different subclasses), the likelihood of two randomly selected individuals expressing the same panel of MHC antigens is remote in the extreme. Thus, the MHC antigens expressed by an individual to a very large extent define the property of self. This is particularly true for T cells. During the process of maturation in the thymus, nascent T cells undergo a rigorous selection process, and only cells displaying an antigen receptor that has a weak binding affinity for one or more self-MHC antigens are permitted to complete their differentiation into mature T cells. Cells with no affinity for self and cells with too strong an affinity, i.e., strong enough to activate a T cell on its own, are destroyed. When a foreign

peptide is inserted into the cleft of an MHC molecule, its affinity is altered. A small number of T cells, perhaps one in half a million, will bind to this altered MHC with a high enough affinity to activate. Thus, T cells are able to recognize and respond to minute changes in the normal display of self, as represented by an individual's unique collection of MHC molecules.

There are two general effector mechanisms for CMI. The first, cytotoxic T-cell-mediated lysis, is mediated primarily by the subset of T cells that express the protein CD8 on their surfaces. These T cells are restricted to their recognition of foreign peptide on the surface of a class I MHC molecule, which are present on most of the body's cells. Once activated, these cells recognize their specific combination of foreign peptide and MHC on a target cell and have two methods for dispatching the target. The first involves the deposition of perforin pores, which bear a striking resemblance to the terminal complement complex, onto the surface of the cell. The second approach is to induce apoptosis in the target, directing the cell to essentially commit suicide. Both processes result in the destruction of the target cell. Cytotoxic T lymphocytes (CTL), by virtue of their ability to discern the presence of foreign peptides from microbial pathogens inside of a cell, are ideally suited for the elimination of intracellular parasites such as viruses. They are also considered to have an important role in the elimination of tumor cells.

Another CMI mechanism is mediated primarily by the other main subpopulation of T cells, those that express the protein CD4 on their surface. These T cells are restricted in their recognition of foreign peptides on class II MHC molecules. Class II MHC antigens are normally expressed on only a few populations of cells in the body, chiefly B cells, macrophages, and dendritic cells. All of these cell types are capable antigen-presenting cells, since $CD4^+$ T cells also have the central role in the regulation of T-cell responses; the limited expression of class II antigens in the body is thought to reflect a safety restraint aimed at limiting the responsiveness of immune cells. In addition to providing helper activity to both B and T cells, $CD4^+$ T cells are typically recruited to the site of tissue damage and infection, where they coordinate and amplify the effectiveness of both specific and nonspecific arms of the immune system.

10.4. Cellular Interaction in Immune Responses

The immune system is arrayed with an arsenal of weapons capable of causing colossal destruction of tissues if left unchecked. While it provides an invaluable service in the defense against microbial invasion and the spontaneous development of neoplastic cells, extremely tight controls are required to ensure that its activities do not escalate to the point where they become deleterious to the host. As such, the level of intercellular interaction in the immune system is extraordinarily high. As mentioned previously, B-cell responses are generally not possible in the absence of T-cell help. If specific cytokines, such as IL-2 for proliferation, are not made available to the antigen-stimulated B cell, a suboptimal response will result. The generation of T-cell help, in turn, is absolutely dependent on the presence of a suitable antigen-presenting-cell-bearing peptide on a class II MHC antigen. Thus, the participation of at least three different cell types is required to mount an effective immunoglobulin response to antigen. Similarly, a CTL response requires the participation of both a helper T cell and an antigen-presenting T cell for the activation of both T-cell help and the naive CTL.

These cellular interactions take place in at least two ways. Transmembrane surface proteins on both participating cell types may come into direct physical contact, potentially sending an activation signal across the cytoplasmic membrane into both cells. An alternative unidirectional signaling method is to produce soluble hormone-like proteins known as cytokines that bind to a specific ligand on their target cell and send an activation signal across the membrane. A large number of cytokines have been identified and characterized, and each cytokine typically has more than one activity, often depending on the type of cell it engages.

Cellular interactions are not limited to the activation of immune responses. When a threat to bodily integrity has been eliminated, there is no continued need for a response. The action of down-regulating immune responses is termed *immune suppression*. T cells are also the critical regulators for immune suppression. Many of these functions of immune regulation appear to be performed by discreet subpopulations of specialized T cells. At last count, there are at least several functionally distinct subsets of helper T cells, a similar number of suppressor T cells, and so forth. In addition, functionality among T cells does not appear to be set in stone. There are circumstances in which $CD4^+$ T cells perform cytotoxic function and population of $CD8^+$ T cells that serve various regulatory functions. Thus, the complexity of interaction among cells in the human immune system is quite high, and a meaningful discussion of the current, admittedly limited, level of understanding of those interactions is beyond the scope of this overview. Suffice it to say that, under ordinary circumstances, these interactions serve as a system of controls that ensure the immune system will mount a transient, surgical strike against any disease threat.

Occasionally, elements of the interregulatory network break down, sometimes leading to autoimmune disease, a condition in which the immune system causes damage to

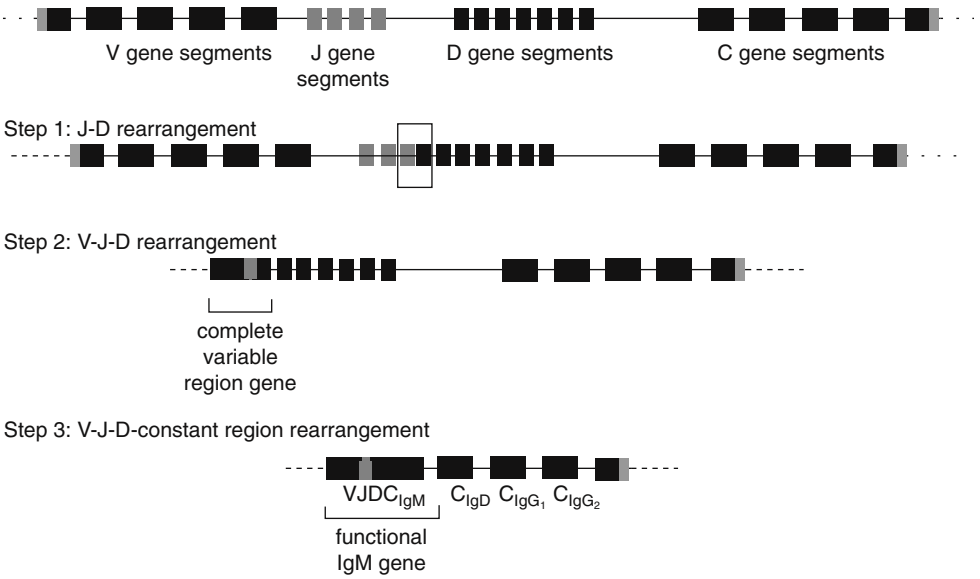

Figure 3. Immunoglobulin heavy chain gene cluster.

various host tissues. Such diseases include type I diabetes, rheumatoid arthritis, and systemic lupus erythematosus. Autoimmune diseases run the gamut from chronic disabling conditions to life-threatening diseases.

10.5. The Generation of Diversity in Antigen Recognition

The immune system presents a great enigma that was a matter of pure philosophical speculation until only two decades ago, namely how does the body go about the business of preparing a population of cells, each of which bears a distinct receptor for one of as many as a billion different antigens, none of which it has ever seen before? The two extremes of the philosophical argument went as follows: (1) One's genetic material contains the information required to encode all one billion different specificities for foreign antigen, and selects from that collection of genes in a random fashion; and (2) the genetic material encodes for only a few antigen receptor genes and the rest of the diversity results from extraordinarily high rates of mutation. The interesting feature of these two "obvious" solutions to the enigma is that neither of them came terribly close to the truth.

Immunoglobulin genes and T-cell receptor genes are arranged in clusters of subsegments, as shown in the illustration of an immunoglobulin heavy chain gene map (Figure 3). The immunoglobulin genes and T-cell receptor genes are assembled from randomly selected segments into a single functional gene. The construction of variable region (which encodes the antigen binding site) of a heavy chain gene, for example, would involve the co-alignment of one of approximately 1,000 V gene segments, with one of four J-segment genes and one of 12 D-segment genes. This results in $1{,}000 \times 4 \times 12 = 48{,}000$ possible heavy chain variable gene segments. The various segments are aligned through intrachain recombination events. Recombinational diversity for the immunoglobulin light chains is somewhat more limited, providing for approximately 1,000 different light chain variable genes. Since every functional antibody molecule is made up of two identical light chains and two identical heavy chains, the number of different combinations becomes $1{,}000 \times 48{,}000$ or 480,000. Added to that is the fact that the junction sites between V, J, and D segments vary, leading to junctional diversity due to single base substitutions and even short frame shifts. Finally, the mutation rate in the immunoglobulin gene cluster is approximately fivefold that of normal mutation rates. All of this is estimated to provide potential for diversity in the antibody population on the order of a billion different specificities. The T-cell receptors rearrange similarly.

11. Patterns of Host Response

The clinician usually deals with persons already ill with an infectious disease severe enough for them to seek medical care. The epidemiologist must study not only those clinically ill but also the full range of host responses that follow infection. These can vary quantitatively from inapparent infection

to severe illness to death in what is called a *biological gradient*. They can also vary qualitatively in different signs and symptoms that make up different clinical syndromes. The detection of persons with inapparent or subclinical infection requires laboratory tests to detect the presence of antibody or antigen.

11.1. Biological Gradient

When a susceptible host is exposed to a source of infection, a wide range of quantitative responses may occur.[4] These are often depicted as an iceberg, as shown in Figure 4, with the largest number of responses occurring subclinically, below the waterline of clinical recognition. The right side of Figure 4 represents the responses of the host. These range subclinically from exposure without successful attachment or multiplication of the bacterial organism, to colonization without tissue injury, to infection that evokes a host immune response but no clinical disease. The existence of these inapparent events can be recognized only by laboratory means such as isolation of the organism or measurement of the immune response. In viral infections, the ratio of inapparent–apparent (subclinical–clinical) infection has been determined through prospective studies correlating the number with an antibody response to the number clinically ill. The occurrence of inapparent infections is also suggested in persons with antibody but no history of clinical disease. Some information has also come from the rate of secondary infection in families with an index case and from volunteer studies. This type of information is not available for many bacterial infections because serological techniques are not as useful and/or widely employed in measuring infection rates, but a few examples may be cited. In leptospirosis, serological tests of persons heavily exposed (veterinarians, abattoir workers) but without known illness have shown an antibody prevalence of 16%. This suggests that only 16 of 100 exposed persons have been infected as manifested by an antibody response. There are no data for leptospirosis indicating the subclinical–clinical ratio, but of those clinically ill, 90% or so have an acute, self-limited illness without jaundice and with good prognosis; the overall case-fatality rate in 791 cases reported to the CDC from 1965 to 1974 was 7.7% (see Chapter 20). In tuberculosis, it was estimated that of the 50,000 clinical cases reported in 1963, 80% came from the 24 million infected in previous years and 20% from persons infected the same year (see Chapter 39).

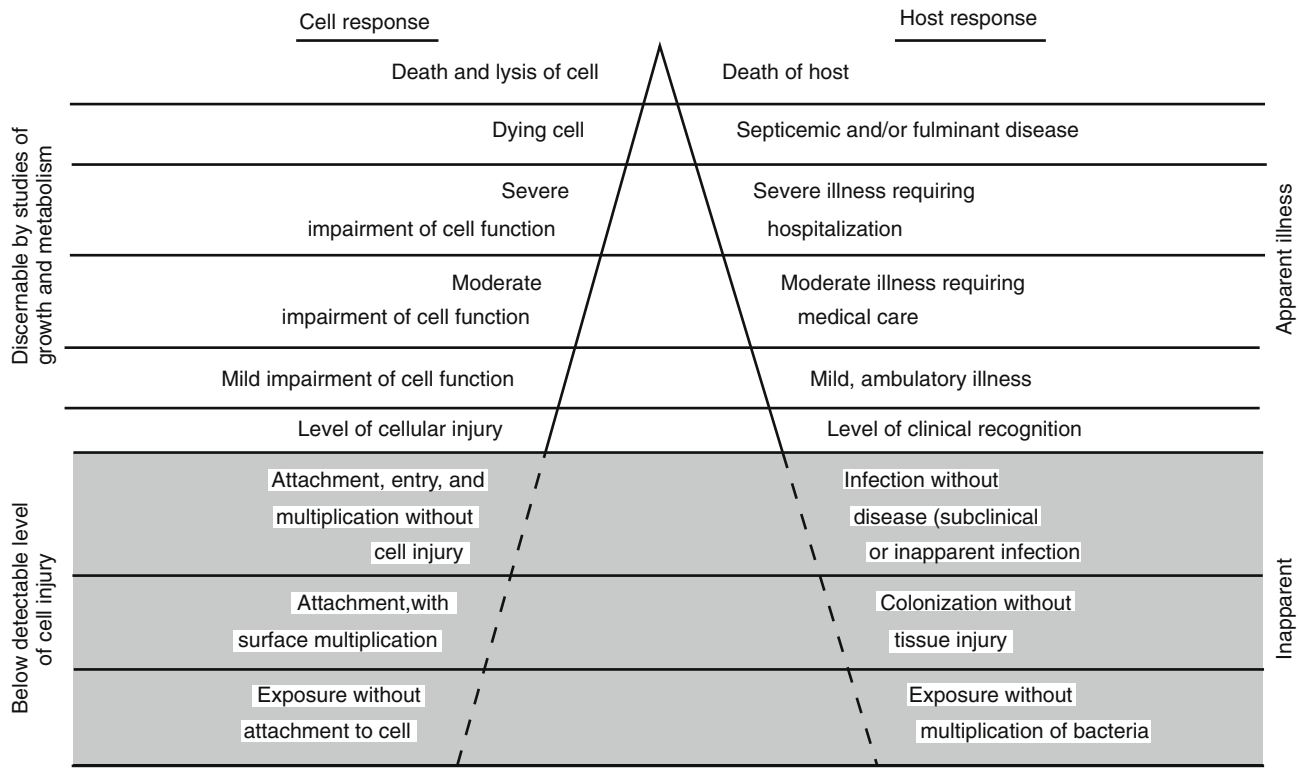

Figure 4. Biological spectrum of response to bacterial infection at the cellular level (*left*) and of the intact host (*right*).

In summary, a wide range of quantitative and qualitative responses can occur on exposure to a pathogenic organism. The determinants of this pattern lie both in the pathogenicity and virulence of the infecting organism (see Section 4) and in the age, genetic makeup, immune response, portal of entry, and other characteristics of the host (see Section 6).

The left side of Figure 4 is a simplistic expression of the response to bacterial infection at the cellular level. Cell injury may result from enzymes and other metabolic products of bacteria, from toxins produced by them, from entry and multiplication of the organisms intracellularly, as with *M. tuberculosis, M. leprae, B. abortus*, or as a consequence of the phagocytic and immunologic defense mechanisms induced by the infection. Epidemiologically, the message is that most organisms do not result in cell dysfunction or death and that the healthy person lives in symbiosis with millions of bacteria.

11.2. Clinical Syndromes

The host can show qualitative as well as quantitative differences in response to the same bacterial infection. These qualitative responses are manifested by different clinical syndromes, the patterns of which depend on the portal of entry of the organism, age of the host at the time of infection, immune status, and other factors. This variation is not as great with bacterial infections as with viral infections. Many bacterial infections such as anthrax, cholera, diphtheria, leprosy, pertussis, tetanus, tularemia, and typhoid fever present with fairly characteristic clinical features that vary quantitatively, but not qualitatively, from host to host, and a diagnosis can often be made on clinical grounds alone. Others, such as streptococcal infections, leptospirosis, syphilis, tuberculosis, and Lyme disease, may involve different tissues and organs in different persons, resulting in different clinical presentations, often depending on the site of infection and the age group involved. On the other hand, there are many clinical syndromes of diverse cause in which etiologic diagnosis is difficult on clinical grounds alone. It is here that epidemiological probabilities will help clinical judgment. Infections of mucosal and serosal surfaces fall into this category because of the limited spectrum of local responses that can result. These can involve the meninges, respiratory tract, intestinal tract, urinary system, and urethra. Invasion of the bloodstream (septicemia) by different bacteria also invokes a common group of signs and symptoms that may be difficult to differentiate etiologically.

This section will present some of the common causes of these clinical syndromes that may vary with the age of the person at the time of infection. Knowing the most common causes in a given age group may help to establish a tentative diagnosis and to initiate proper treatment.

11.2.1. Infections of the CNS. Meningitis is a common clinical syndrome caused by bacteria, viruses, fungi, and protozoa. The clues that suggest bacterial infections are polymorphonuclear leukocytosis in blood and cerebrospinal fluid (CSF) (500–20,000/mm^3), low CSF glucose concentrations (usually $<$35 mg/100 ml or CSF–serum ratio$\leq$0.5), elevated CSF protein (80–500 mg/100 ml), and in about 75%, the presence of bacteria in the Gram-stained smear of a centrifuged sample of CSF. These findings characterize purulent meningitis, but may be altered by treatment with antibiotics so that they resemble nonpurulent bacterial infections, such as *M. tuberculosis* and leptospirosis, or viral meningitis. The etiologic agents that produce meningitis in different age groups will vary some by geographic area, year, and socioeconomic level.

The age-specific incidence per 100,000 of various types of meningitis by age group is presented in Table 9 from an excellent review article on the diagnosis and management

Table 9. Annual Age-Specific Incidence of Meningitis, United States, 1978–1981[a]

Age	*Neisseria meningitidis*	*Haemophilus influenzae*	*Streptococcus pneumoniae*	Group B *streptococcus*	*Listeria monocytogenes*	Total meningitis
$<$1 mo	2.0	6.7	3.5	44.6	7.6	99.5
1–2 mo	9.1	18.6	5.7	10.0	1.3	56.7
3–5 mo	11.5	52.0	11.6	1.4	0.1	83.3
6–8 mo	10.6	65.1	8.0	0.3	0	88.4
9–11 mo	7.9	48.1	4.7	0	0.1	63.3
1–2 yr	3.8	19.0	1.5			25.3
3–5 yr	1.8	3.9	0.5			6.8
5–9 yr	0.7	0.7	0.3			2.0
10–19 yr	0.6	0.1	0.1			1.0

[a]Results are reported as numbers of children with meningitis per 100,000 population.[48] Data were provided by C. V. Broome, Centers for Disease Control, Atlanta, and by Schlech et al.[49]

of meningitis by Klein et al.,[48] which incorporates data from the CDC and a National Surveillance Study by Schlech et al.[49] The overall incidence of meningitis is highest in the newborn, drops in the first 2 months of life, and then rises to high levels between 3 and 8 months of life. Based on a National Surveillance Study of 18,642 cases reported from 1973 to 1981, *H. influenzae* accounted overall for 48.3% of the cases, *N. meningitis* for 19.3%, and *Streptococcus pneumoniae* for 13.3%, totaling 81%.[49] Rates in males exceeded females (3.3 vs. 2.6 per 100,000). By age, the most common causes were as follows: in the newborn, group B streptococcus and *E. coli*; in infants, *H. influenzae* type b and *N. meningitidis*; in toddlers, similar to the newborn; and in schoolchildren and adolescents, *S. pneumoniae, N. meningitidis*, and *H. influenzae* are the major pathogens in the decreased number of cases in that age group. An analysis of 493 episodes in 1993 of bacterial meningitis in hospitalized adults over 16 years of age in a Boston hospital from 1962 to 1988 revealed that 40% were of nosocomial origin with a mortality of 35%.[50] The risk factors included age $\geq$ 60 years, obtunded mental state on admission, and seizures within the first 24 h. Gram-negative bacilli (other than *H. influenzae*) caused 33% of these episodes. Of 296 community-acquired meningitis cases, *S. pneumoniae* accounted for 37%, *N. meningitides* for 13%, and *L. monocytogenes* for 10%. Only 4% of all episodes were due to *H. influenzae*.[50]

The characteristics of the organisms involved and the patterns of disease can be found in the individual chapters of this book. Suffice it to mention here that in the newborn, most cases of group B streptococci are due to subtype III, and that infection usually arises from vaginal and rectal infections of the mother that can lead to a 40–70% infection rate in the newborn; the K1 antigen of *E. coli* is involved in 75% of neonatal meningitis, and *L. monocytogenes* is becoming increasingly important in meningitis in this age group in several areas of the country.[48] In children beyond the newborn period, head trauma may precede the onset of meningitis and organisms may then enter through the cribiform plate or the paranasal sinuses. Meningitis may also follow neurosurgical procedures or osteomyelitis of the skull or vertebral column.

Acute bacterial meningitis is a medical emergency, and it is most important to establish the identity of the infecting organisms as quickly as possible as a guide to antibiotic therapy. However, until this is done, a Gram-stained smear of the CSF should provide a reasonable basis for initial chemotherapy.

11.2.2. Acute Respiratory Infections. These represent the commonest causes of morbidity in the developed world. Their importance as a cause of both morbidity and mortality in developing countries has now been recognized, and major programs of control have been initiated under the auspices of the WHO. In developing countries, it is estimated that over 4.5 million children under the age of 5 years die annually of acute respiratory tract infections (ARI), which represents some 30% of the 14 million deaths in this age group yearly.[51–54] The commonest causes are *S. pneumoniae* (see Chapter 34) and *H. influenzae* (see Chapter 16). A study of respiratory infections in children aged 0–59 months in several different developing countries revealed rates of 12.7–16.8 new episodes of ARI per 100 child-weeks at risk and 0.2–3.4 for lower respiratory tract infections.[55] Case management intervention strategies using community health workers have helped reduce the mortality, but many gaps remain in our understanding of the etiology, epidemiology, and pathogenesis of these conditions.

Fewer than 10% of acute upper respiratory infections (AURIs) are due to bacteria in either developed or developing countries, although in the latter, infections with *B. pertussis* (see Chapter 26) and *M. pneumoniae* (see Chapter 24) are important in certain settings. The syndrome of epiglottis in children aged 6 months to 2 years (up to age 6), however, is due to a bacterial pathogen, *H. influenzae* type b in about 90% of cases worldwide. This is often a serious and fulminant infection with a high mortality. A vaccine is now available.

The viruses involved in AURIs in both developing and developed countries are respiratory syncytial virus (RSV) in children under 3 years of age, parainfluenza in older children, and coronaviruses, rhinoviruses, and influenza in all ages.

The syndrome of acute pharyngitis and tonsillitis is due to streptococcal infections, mostly group A, in about one fourth to one third of cases, another one third are due to various viruses, and the remainder are of unidentified cause, although chlamydial infections may play a role in some of these.[56,57] Streptococcal infections can lead to acute rheumatic fever; this disease had been disappearing rapidly in developed countries until very recently when a recrudescence was reported in several areas of the United States. A very invasive streptococcal group A infection producing a toxic shock-like syndrome has recently been described in several parts of the world[58,59] (see Chapter 38). In developing countries, some 1.2 episodes of rheumatic fever are said to occur for every 1,000 untreated streptococcal infections, but this, too, seems to be decreasing.[52] *C. diphtheriae* (see Chapter 13) is also a cause of exudative tonsillitis in some Third World countries, and a recent outbreak occurred in Sweden involving 17 cases and 3 deaths despite very high immunization coverage.[60]

Acute lower respiratory infections are due mostly to viruses in young children, except for infants, to

M. pneumoniae and viruses in young adults, and to bacterial pathogens in older adults and the elderly. Prospective studies in community settings of developed countries suggest that five agents—RSV, parainfluenza virus, influenza virus, adenovirus, and *M. pneumoniae*—account for some 80% of acute lower respiratory infections in these population groups.[52]

Common respiratory syndromes in young children such as croup, laryngotracheitis, and bronchiolitis are usually due to viruses, especially RSV and parainfluenza viruses. Diphtheria may also cause a croup syndrome when the toxic membrane involves the larynx. Acute bronchitis is most often due to a variety of viral infections, but bacteria such as *M. pneumoniae, B. pertussis*, and *C. trachomatis* (TWAR strain) may also produce this syndrome. Chronic bronchitis, on the other hand, is largely associated with nontypable *H. influenzae* and pneumococci (*S. pneumoniae*).

Pneumonia is the sixth most common cause of death in the United States and has varied causes at varied ages. In infancy (under 6 months), about 30% are now recognized as chlamydial and present as a gradually developing nontoxic illness with cough, pulmonary congestion, rales, and patchy infiltrates on X-ray (see Chapter 10). Chlamydial genital infection of the mother carries a 10–20% risk of pneumonia in her infant. In another study of 205 infants under 3 months old hospitalized with pneumonitis, Brasfield et al.[61] identified a causal agent in 70%. *C. trachomatis* was found in 36%, RSV in 23%, cytomegalovirus in 20%, *Pneumocystis carinii* in 17%, and *Ureaplasma urealyticum* in 16%. In older children, the causes of pneumonitis and pneumonia are roughly one fourth viral, one third unknown cause, and the rest bacterial. More careful bacteriological culturing techniques have identified a bacterial etiology in 15–50% of this age group: pneumococci (*S. pneumoniae*) are the most common organism, and *H. influenzae* next most common; rarely, *S. aureus* and group A streptococci are involved.

A review of the bacteriological aspirates in children with pneumonia from many countries revealed a bacterial agent in 62% of 1,029 cases: *H. influenzae* and *S. pneumoniae* accounted for 54% of all isolates, while *S. aureus* was responsible for 17%.[52] Viral infections were associated with 17–40% of pneumonia in hospitalized children in several developing countries.[52] The true role of *Chlamydia* and *M. pneumoniae* infections in childhood respiratory infections in developing countries has not been well studied yet because of technical problems with the laboratory diagnosis, but it seems likely they may play as important a role as in developed countries. Community studies of *M. pneumoniae* pneumonia have shown the highest incidence in school-age children, with a decline after puberty, and with the lowest rates in the over 40-year-old age group, possible reflecting immunity. However, some 25–50% of pneumonia in young adults, such as college students, is due to this organism, and infection rates are high in military recruits (see Chapter 24). In a long-term study of some 15,000 episodes of pneumonia in a group health plan in Seattle, about 45% were tested for *M. pneumoniae* by isolation and serological tests, and 15% were found to be due to this agent, with the highest rate in children.[62] A new chlamydial strain, designated as TWAR (for Taiwan acute respiratory), has been shown to be an important pathogen in acute respiratory infections such as pneumonia, bronchitis, sinusitis, as well as mild upper respiratory infections.[63,64] In a retrospective examination of 200 patients from a group cooperative study,[62] 8% were due to this organism, which is a rate of 1 per 1,000 per year and with the highest incidence in the elderly. Only about 2% of patients with *M. pneumoniae* require hospitalization, and infection with *Chlamydia pneumoniae* is usually mild or asymptomatic. The secondary intrafamilial infection rate is high after an index case of *M. pneumoniae* is introduced and involves about 84% of children and 41% of adults.

In adults, especially older adults, most pneumonias are bacterial in origin. In the past, *S. pneumoniae* caused 50–90% of community-acquired pneumonias, but in recent years this has decreased to some 16–60%, still the dominant organism.[65–67] In an excellent prospective study of 359 community-acquired cases of pneumonia admitted to three Pittsburgh hospitals in 1986–1987, the most frequent etiologic agents were *S. pneumoniae* (15.3%), *H. influenzae* (10.9%), *Legionella* spp. (6.7%), *C. pneumoniae* (TWAR) (6.1%), and gram-negative organisms (6%).[65] In 32.9%, the etiology was indeterminate. No distinctive clinical picture was diagnostic for any etiologic agent. The underlying illnesses were immunosuppression (36.3%), chronic obstructive pulmonary disease (32.4%), and malignancy (28.4%). The median age was 62 years. The mortality was 13.7% and was highest for *S. aureus*. For most cases, erythromycin therapy would be effective. In recent years, gram-negative organisms are of increasing importance, perhaps causing 7–18% of pneumonia, and of special importance in the elderly. Some 30–40% of community-acquired pneumonias are of unknown etiology, due perhaps to 30% of persons unable to produce sputum for culture, or one third who have received antibiotics before hospitalization, or in about one fourth the organisms are difficult to isolate, such as *M. pneumoniae, C. pneumoniae, Coxiella burnetti*, and *Legionella* species, as well as viruses. Even invasive diagnostic techniques in three studies left 43% of unknown etiology, 8% were polymicrobial, and 49% were due to a wide variety of pathogens that varied according to geographic region.[67] Antibiotic-resistant organisms and toxic streptococcus are emerging pathogens in pneumonias, and *M. pneumoniae* is appearing as a pathogen in the elderly.[68]

11.2.3. Acute Otitis Media. This is a common infection of children, with a peak age of 6–18 months. It occurs seasonally throughout the year, but is highest in fall and winter.

Family aggregation is common for recurrent disease. Accurate diagnosis is dependent on cultures taken by aspiration from the middle ear. A recent review of etiology by Klein[69] reports that a bacterial antigen was isolated from two thirds of such aspirations: *S. pneumoniae* was the leading cause in 25–50%, then nontypable *H. influenzae* in 15–30%, *Moraxella catarrhalis* in 3–20%, group A streptococci and staphylococcus in 2–3%, and viruses alone or with bacteria in about 33%. *M. pneumoniae* was uncommon in middle-ear infections in most children. In children under 6 months, *C. trachomatis* with acute respiratory infections was found to be associated with middle-ear infections. It is important to emphasize that the etiology cannot be diagnosed by the clinical picture alone and that culture of aspirated material from the middle ear is needed.

11.2.4. Intestinal Infections and Intoxications. These may be divided into foodborne poisons and intestinal infections.

11.2.4.1. Bacterial Food Poisoning. While this section is concerned with bacterial causes, it is important to emphasize that Norwalk and Norwalk-like viruses are probably one of the major causes of both food- and waterborne outbreaks worldwide.[70] Bacterial food poisoning is dealt with in more detail in Chapter 5. In an analysis of 2,841 outbreaks of known etiology from 1973 to 1987 reported to the CDC and which involved 124,824 persons, 66% were caused by bacterial pathogens, 25% were due to chemicals, 5% to parasites, and 5% to viruses. The major contribution of bacterial etiology to the 124,824 cases was *Salmonella* (45% of total), involving 55,864 cases in 790 outbreaks; *S. aureus* (14% of total), involving 17,248 cases in 367 outbreaks; *Shigella* (12% of total), involving 14,399 cases in 104 outbreaks; and *C. perfringens* (10% of total), with 12,234 cases in 190 outbreaks. *C. botulinum* was reported in 231 outbreaks (8%) and affected 494 persons.[71] It should be emphasized that food outbreaks are greatly underreported.

11.2.4.2. Intestinal Infections. The causes of enteric infections vary with age and geographic area. They are perhaps the most common cause of morbidity worldwide, rivaling acute respiratory infections. In this book, they are dealt with under *Campylobacter* (Chapter 8), cholera (Chapter 11), *C. difficile* (Chapter 12), *E. coli* (Chapter 14), *Helicobacter pylori* (Chapter 17), salmonellosis (Chapter 31), shigellosis (Chapter 32), typhoid fever (Chapter 42), and yersiniosis (Chapter 43).

The magnitude, special settings, and etiology of diarrhea in both developing and developed countries have recently been reviewed.[72] The incidence in developed countries is estimated as 1–3 illnesses per person per year and 5–18 illnesses per child per year in tropical, developing countries. An estimated 12,600 deaths per day occur in children in some of these developing areas of Asia, Africa, and Latin America. In all countries the peak incidence is in young children, usually under age 3 years and often earlier in developing countries. The causes involve bacteria, viruses, and parasites, and sophisticated laboratory techniques are required to diagnose some of them, thus making definitions of etiologic patterns difficult in areas without modern laboratory facilities.

In children, viruses play a predominant role in some seasons, and the rotaviruses may cause about half the cases of acute diarrhea in children under age 3 years on a worldwide basis. In older children and adults, Norwalk-like agents are important, and intestinal adenoviruses are increasingly being recognized in young children. Among the bacterial pathogens, enterotoxic *E. coli* is probably the most common, with its production of both the cholera-like LT toxin and the ST toxin.[72]

In travelers, *E. coli* (ETEC) is also the most common cause and is found in 42% of diarrheal episodes in Latin America, 36% in Africa, and 16% in Asia.[42] The enterotoxigenic form has been found in 15–30% of illnesses in the community or in hospitals, especially in tropical, developing settings, and is also common in adults in these areas.[72] *C. jejuni* is perhaps the most common cause of inflammatory diarrhea in developed countries and *H. pylori* is increasingly recognized as a cause of gastritis, peptic ulcer disease, and probably gastric carcinoma.[73,74] The organism can be eliminated in 80–90% of infections by treatment with bismuth and antibiotics, and such therapy is routinely recommended for gastric ulcers.[75]

Diarrhea is increased in incidence in certain special settings. The importance of nosocomial diarrhea is being increasingly recognized. It accounted for 17% of all nosocomial infections in a children's hospital in Buffalo[76] and 42% in an adult intensive care unit in a London hospital.[77] The etiology of nosocomial diarrhea as reported to the CDC from 1980 to 1984 was *C. difficile* in 45.1% and *Salmonella* species in 11.8%.[72] In extended care facilities for the elderly, diarrhea is also an important problem, where about one third of patients experience a significant episode each year, and *C. difficile* is a common cause. Outbreaks of diarrhea in child care centers are also common, and frequent causes include rotavirus, *Shigella, C. jejuni, C. difficile, G. lamblia*, and *Cryptosporidium*. High attack rates are seen with rotavirus and some bacterial infections. Finally, some 50–60% of patients infected with HIV in the United States have diarrhea at the onset of illness, and initial

diarrhea is seen in over 90% of AIDS patients in Africa and Haiti.[78] A wide variety of organisms may be involved, of which *Cryptosporidium* is the most frequent, accounting for 3–21% in AIDS patients in the United States and 50% in Africa and Haiti.[78] This organism may also produce diarrhea in normal persons and its contamination of a public water supply in Milwaukee resulted in a massive outbreak involving over 403,000 persons.[28]

As mentioned above, *Campylobacter* enteritis is an increasingly recognized cause of intestinal infections in the United States, Great Britain, and Australia, accounting for some 5–14% of the cases in several large series (see Chapter 8). The clinical disease is characterized by watery diarrhea with mucus, blood, or pus, often cramping abdominal pain and fever, and sometimes gross blood in the stools of children. *Y. enterocolitica* is another recently recognized cause of acute diarrhea attended by some cramps, fever, and occasionally a rash; the incubation period is 1–3 days. There may be associated mesenteric adenitis, arthritis, and erythema (see Chapter 43).

The prevention of traveler's diarrhea is important because some 40% of travelers from developed countries with temperate climates will develop diarrhea, as reviewed by DuPont and associates.[43,79,80] The use of bismuth subsalicylate has proved useful in the short term and antibiotic prophylaxis and treatment is recommended for longer exposures. The following recommendations are quoted from DuPont et al.[79]:

> In most cases a bacterial pathogen is responsible for the illness. The antimicrobial agents with the greatest activity against these organisms are cotrimoxazole (trimethoprim/sulfamethoxazole) during the summer months in the interior of Mexico (a region where this agent has been studied extensively), and the fluoroquinolones for other places or other times, until data become available to indicate the appropriateness of cotrimoxazole here as well. Persons at risk should take along with them a drug to treat symptoms of travelers' diarrhea, and an appropriate antimicrobial agent. At the passage of the third unformed stool, it is recommended that travelers treat themselves with fluids and salt (flavored mineral water augmented with saltine crackers is sufficient in most cases), symptomatic treatment and antibacterial therapy. Of these, the antimicrobial is the most important component, which is given either as a single large dose or once or twice daily for 3 days. Perhaps optimal therapy for afebrile nondysenteric patients is loperamide in combination with the antibacterial drug. In the face of fever or dysentery, the antimicrobial should be used alone. In special situations where food and beverage restrictions cannot be followed and where the itinerary cannot tolerate even the slightest alterations because of illness, chemoprophylaxis can be considered. The most effective preventive medication in this case is the antimicrobial also used for therapy, taken in half the therapeutic dosage daily while in the area of risk. However, the majority of travelers should not use this approach.

11.2.5. Acute Urinary Tract Infections. In various studies of acute urinary tract infections (UTI) of inpatients and outpatients, *E. coli* is by far the most common organism in both settings, accounting for up to 80% of initial urinary infections in outpatients.[81] In a more recent compilation of etiologic agents in hospitalized cases, Andriole[82] found 35.8% due to *E. coli*, 16.4% due to *P. mirabili*, 16.3% due to *Enterobacter aerogenes*, 10.1% due to *K. pneumoniae*, and less than 6% each due to other causes. Over 80% are associated with use of urethral catheters. The spectrum of urinary infections varies and each syndrome has its own unique epidemiology, natural history, and clinical manifestations.[83] The major risk factors include the newborn (particularly the premature), prepubertal girls, young boys, sexually active young women, elderly males, and elderly females. Risk factors that contribute to lower tract infection in women include sexual intercourse, diaphragm–spermicide use, and voiding behavior.[84] UTI is the most common infectious disease of the elderly and is especially prevalent in debilitated, institutionalized older individuals. Unlike UTI in younger women, which tends to be related to frequency of sexual intercourse and is uncomplicated, in the elderly it is more difficult to treat and its pathogenesis is related to abnormal bladder function, bladder outlet obstruction, vaginal and urethral atrophy, use of long-term indwelling catheters, and puddling related to bed rest. The spectrum of organisms causing infection relates to the ecology of the patients' environments; those residing in nursing homes, and especially with permanent indwelling catheters, tend to have a greater variety of pathogenic organisms, many of which may be relatively antibiotic resistant.[85]

The immediate diagnosis of UTI is based on relatively simple techniques. The presence of pyuria and bacteriuria, the two most important indicators of UTIs, is most accurately determined by standard techniques. In quantitating pyuria, the finding of 10 leukocytes/mm^3 of urine by either hemocytometry or direct microscopy correlates highly with symptomatic, culture-proven UTIs.[86]

11.2.6. Sexually Transmitted Diseases. The term *sexually transmitted diseases* (STD) encompasses the five classic venereal diseases (gonorrhea, syphilis, chancroid, lymphogranuloma venereum, granuloma inguinale), plus other major ones such as HIV-1, HIV-2, human T-cell lymphotropic virus type I (HTLV-I), herpes simplex 1 and 2, papillomaviruses, hepatitis A and B, *C. trachomatis, Candida albicans*, and *Trichomonas vaginalis*. The number of cases and rates per 100,000 of major bacterial causes of STDs reported to state health departments in 1988 and 1992 are given in Table 10. While *C. trachomatis* infections are among the most prevalent of all sexually transmitted diseases, problems in diagnosis, lack of public health laws, and other problems have made surveillance of this disease

Table 10. Reported Cases and Rates per 100,000 of Classical Sexually Transmitted Diseases Reported to State Health Departments in the Civilian Population, United States—1988 and 1992[a]

	Number of cases		Rate per 100,000	
Disease	1988	1992	1988	1992
Gonorrhea	738,160	501,409	300.3	201.6
Syphilis (all stages)	104,546	112,541	45.5	45.3
Chancroid	4,891	1,886	2.0	0.8
Lymphogranuloma venereum	194	302	0.1	0.1

[a]Derived from Table 1, in Ref. 87.

incomplete, and therefore it is not included in Table 10. Reflecting increasing recognition and reporting of this infection, the rates per 100,000 have risen from 3.2 in 1984 to 182.6 in 1992 when 36 states reported to the CDC.[87] In large cities with more than 200,000 population the rates were 296.8 in 1992. An estimated 4 million cases occur annually, many of which cause pelvic inflammatory disease with serious sequelae such as ectopic pregnancy and infertility.

It is important to emphasize that many of these STDs occur in synergy with HIV infection and that the transmission of both is enhanced in the presence of the other. Overall, the trends in recent years show that reported rates for gonorrhea have declined 19%, with rates decreasing from 250 per 100,000 in 1991 to 202 per 100,000 in 1992, and with declines in primary and secondary syphilis rates from 17.3 to 13.7 in the same period. This decline may reflect the adoption of safer sexual practices. The proportion of adolescent women aged 15–19 years who reported having sexual intercourse, however, increased from 29% in 1970 to 52% in 1988.[88] The rates of gonorrhea and syphilis in the adolescent age group are three times that of the general population, and thus are a major target for education and control. The risk for STD is also much higher in blacks than in whites, with rates for primary and secondary syphilis being 60-fold higher and for gonorrhea 40-fold higher; for Hispanics the increases are fivefold and threefold higher, respectively.

Adequate surveillance data are not available for several sexually transmitted diseases. Some information of trends is seen in the office practice of certain physicians based on the National Disease and Therapeutic Index as analyzed in graphs in a CDC report.[87] For human papillomavirus genital warts, physician visits in this survey have risen from about 45,000 in 1966 to 200,000 in 1992. Trichomonal infections have declined slowly over this period, starting with 500,000 in 1966, but other vaginal infections have increased sharply from about 120,000 to 3,000,000.

Many of the newer agents of STD account for as many as or more infections seen in STD clinics or by private physicians than are accounted for by the classic causes. These infections are most common in the 15- to 30-year age group—the time of greatest sexual activity, especially extramarital. They are more commonly diagnosed in men, both because men tend to have more sexual partners than do women (except prostitutes) and because the lesions are more apparent in men. Multiple infections are common in both sexes, and gonorrhea and syphilis should be excluded by appropriate examination in every patient seen with an STD. The changing nature of and the increase in these infections have several causes, including the use of measures other than the condom for contraception, changing practices in heterosexual and homosexual activities, especially involving genital–oral and genital–anal contact, the importation of infection from Southeast Asia, and increased public confidence in the availability and effectiveness of antibiotic therapy.

The increasing importance of *Chlamydia* infections deserves further emphasis. Chlamydial genital infections include urethritis, acute epididymitis in men, and pelvic inflammatory disease in women; these are discussed in Chapter 10. Overall, about half the cases of urethritis in men are nongonococcal, and among male college students, this rises to 80–90%. *C. trachomatis* (immunotypes D–K) is responsible for 30–50% of symptomatic cases of nongonococcal urethritis (NGU) and is more common in white than in black men and in higher than in lower socioeconomic levels. Its incubation period is longer than that of gonorrhea, and symptoms of urethritis in males may appear 1–2 weeks or longer after penicillin or spectinomycin treatment for gonorrhea, involving one third to two thirds of these men. Oral therapy of NGU with tetracycline or erythromycin hastens recovery. There is no clinical counterpart of NGU in women who develop *Chlamydia* infections of the cervix with or without cervicitis, but this organism may be involved in up to 30% of pelvic inflammatory diseases in females.[89] The other agents of NGU in men are uncertain, although *U. urealyticum* is considered the cause of 10–20% of NGU cases. If laboratory facilities are not available for the diagnosis of *Chlamydia* infections in persons with NGU, both the case and the sexual partner should be treated with appropriate broad-spectrum antibiotic therapy (usually tetracycline or doxycycline) as though they had it. For detailed information on STD infections, see Chapter 9 on chancroid, Chapter 10 on *Chlamydia* infections, Chapter 15 on gonococcal infections, and Chapter 35 on syphilis. Viral causes are discussed in the companion book on viruses.[5]

11.2.7. Hospital (Nosocomial) Infections. These are infections acquired after an admission to a hospital

and are discussed in detail in Chapter 25. More than 2 million patients annually in the United States develop nosocomial infections. In the largest study to date, 5.7% of 159,526 patients in 338 hospitals developed a nosocomial infection.[90] Each such patient stayed an average of four extra days in the hospital, paying an extra $2,100 for each infection. Some 19,027 deaths were directly attributable to a nosocomial infection and it was a contributory factor in 58,092. In reports to the CDC's National Nosocomial Infections Surveillance program in 1991–1992, which involves 149 hospitals, urinary tract infections were the most common site (33.1%), followed by pneumonias (15.5%), surgical site infections (14.9%), and primary bloodstream infections (13.1%), and this order was similar irrespective of the size of the hospital. Among 71,411 isolates from all sites, *E. coli* and *S. aureus* were the most common (12% each), followed by coagulase-negative staphylococcus (11%), *Enterococcus* spp. (10%), *Pseudomonas aeruginosa* (9%), *Enterobacter* spp. (6%), and all other organisms 5% or less.[90] Unfortunately, the major nosocomial pathogens either are naturally resistant to clinically useful antibiotics or are potentially able to develop resistance. This includes both gram-positive organisms (*S. aureus, Enterococcus* spp.) and gram-negative organisms (*K. pneumoniae, P. aeruginosa*, and *Enterobacter* spp.).

12. Diagnosis of Bacterial Infections

Identification of the causal agent is essential to establish the etiology of a bacterial infection and as a guide to selecting appropriate antibiotic therapy. It depends primarily on (1) microscopic examination of exudates, body fluid, or tissues after staining (Gram's stain, acid-fast), or by dark-field examination or immunofluorescent-labeled antibody tests, or by the newer techniques for antigen identification such as counterimmunoelectrophoresis and latex agglutination, as used in respiratory infections; (2) appropriate bacteriological culture techniques; (3) a variety of new techniques to identify the antigen and a particular antigenic strain, many based on molecular methods; and (4) serological tests. Serological tests are not as commonly employed as in viral infections because of the ease and rapidity with which the diagnosis can often be established by smear and culture for most bacterial infections. For slow-growing or difficult-to-culture organisms such as *L. pneumophila*, the spirochetes, and the rickettsiae, serological tests play an important role in diagnosis. Animal inoculation may be required to identify fastidious organisms and the toxins of certain bacteria, and skin tests may be useful to diagnose infections that show delayed hypersensitivity.

This section will briefly review some of these techniques, but for more definitive information, see textbooks on laboratory methods,[91,92] medical microbiology,[32] or clinical infectious diseases.[38] An informative pamphlet on the services available from the CDC for the diagnosis of diseases of public health importance is available that indicates specimen collection, tests done, shipment instructions, and federal regulations on interstate shipment of etiologic agents.[93] All such specimens with proper justification and a completed request form must be submitted to the National Center for Infectious Diseases of the CDC in Atlanta by or through the state health laboratory with the knowledge and consent of the state laboratory director or designee.

An important decision for the physician is the differentiation of bacterial from viral infections on first examination in order to decide on the necessity of antibiotic therapy and as a guide to laboratory tests. This may not always be possible, but the presence of bacterial infections is suggested by the vigor and acuteness of the clinical onset, leukocytosis, and the presence of purulent lesions with polymorphonuclear cells. Nonpurulent responses to bacteria are seen in such diseases as brucellosis, tuberculosis, and typhoid fever. The presence of more than 10 white blood cells/mm^3 of urine by either hemocytometry or direct microscopy is indicative of an acute bacterial urinary infection,[86] as is the presence of white blood cells in the stool of a bacterial pathogen involved in diarrhea, or of polymorphonuclear leukocytes (not lymphocytes) in spinal fluid of a bacterial meningitis.

12.1. Collection of Specimens

The selection of the appropriate site from which to obtain the specimen, its collection prior to antibiotic therapy, and its transport to the laboratory in a manner to preserve the viability of any organisms present are three essential ingredients of successful diagnostic microbiology. The specimen should be taken from the site of the infection or from the body fluid most likely to contain organisms from the infected site. The collection should be made with sterile swabs and collecting units. Cotton applicator swabs are commonly used, but since cotton may be toxic to certain bacteria, a synthetic material such as calcium alginate is preferable. An adequate sample must be obtained to prepare smears and cultures and for special isolation purposes (viruses, fungi). Swabs may be inadequate for this purpose, and the fluid itself, or a washing of it (e.g., throat, nasal, lesion), may be needed for quantitative measurement, as in urine, to determine the number of organisms present. A syringe aspirate is desirable for anaerobic cultures of purulent lesions. Since most large laboratories have special sections for bacterial, viral, fungal, parasitic, and treponemal diagnostic

techniques, separate specimens for each microbiological group considered as a possible etiologic agent in a given infection should be collected. Special techniques may be needed to avoid contamination by normal flora in needle or surgical aspirations from a lesion or from a transtracheal or transurethral site.

To preserve viability, material from patients may be (1) inoculated into appropriate transport media directly at the bedside, for which purpose kits are now commercially available; (2) carried to the laboratory for immediate inoculation; or (3) preserved in a transport medium that maintains viability, prevents desiccation, and limits overgrowth of other organisms; media containing agar and charcoal are commonly employed (Stuart's transport medium or Arnie's modification thereof). If transport media are used, smears should be prepared separately at the time of collection with a separate swab because the agar in the transport medium makes this difficult. If viruses are suspected, a separate specimen should be collected and immediately frozen in dry ice for transport to the laboratory. Blood samples should be collected aseptically in amounts of 10–15 ml. If shipment to a laboratory is needed, the serum should be separated aseptically and forwarded preferably in the frozen state, but this will vary, depending on the infection. Infections of certain sites or with certain organisms may require special collection or transport methods or both; these are described in the appropriate individual chapters in this book or in books on bacteriological diagnosis.

12.2. Requests for Testing

There must be good communication between the physician or epidemiologist and the microbiologist. In the face of an outbreak, the epidemiologist is urged to consult with the laboratory prior to the investigation or have a laboratory specialist accompany the investigator to make the proper specimen collection and method of transporting it to the laboratory. The wide array of specialized laboratory techniques and culture media available makes it necessary that the laboratory be provided with information on a clinical and epidemiological assessment of the etiologic possibilities. The age, sex, clinical diagnosis (or at least the organ system involved), previous antibiotic therapy, and other pertinent patient information plus the site, time, and date of collection and method of transport to the laboratory of the specimen are helpful data to the laboratory worker in pursuit of the correct techniques to be employed. In return, the clinical microbiologist must provide periodic reports to help the physician in selecting appropriate therapy until the organism is fully identified and its antibiotic sensitivity determined.

12.3. Tests Employed

The details of laboratory methods are beyond the scope of this section, but a few comments will be made; specific techniques are mentioned in each chapter. The importance of a properly obtained and thoroughly examined Gram's stain of the exudate or body fluid cannot be overemphasized as a guide to initial therapy. For example, the etiology of some 85% of acute purulent meningitis cases and of many bacterial pneumonias can be identified by smear, especially if capsular swelling occurs in the presence of specific antisera. Simple microscopic examination of an unstained, uncentrifuged specimen of urine that shows bacteria indicates a quantitative bacterial count of 10^4–10^5/ml, and the morphology may point to the proper etiology. The examination of bacteria in fresh preparations or on culture, after staining with specific, immunofluorescent-labeled antisera, provides specific diagnosis of group A hemolytic streptococci, plague bacillus, and *E. coli*; it has also been useful in identifying the organism in acute meningitis, in cervical gonorrhea, and in primary syphilis.

The rapid detection of antigen in body fluids such as respiratory secretions and in urine is now being accomplished by immunofluorescence, counterimmunoelectrophoresis, enzyme immunoassays, DNA probe hybridization, and latex agglutination. Commercial kits are becoming rapidly available for many of these techniques.[94] A number of molecular techniques are now being used for both phenotypic and genotypic identification of organisms and are well reviewed in a recent article.[95] Those used for epidemiological studies of *phenotypic variants* include antibiotic resistance patterns (antibiograms), biotyping, bacteriocin production, serotyping, outer membrane protein analysis, phage typing, immunoblotting, and multilocus enzyme electrophoresis. The limitations of these techniques are that they do not take genetic exchange or mutations into account, are nonspecific, and are not widely applicable. Independent isolates of the same strain may vary in their phenotype. *Genotypic typing* methods are used to identify the genetic composition of the organism by study of chromosomal, plasmid, or transposon DNA. The techniques include plasmid profile analysis, restriction endonuclease analysis, ribotyping, pulsed field electrophoresis, polymerase chain reaction digests, arbitrarily primed polymerase chain reactions, and nucleotide sequence analysis. Variations in the reproducibility and discriminatory power of the two general methods differ; in general, those that involve genotypic methods are better. Their application permits identification of specific patterns of transmission of an organism, differentiation between reinfection and reactivation, and recognition of the geographic distribution of a particular

strain. The epidemiology of antibiotic resistance involves (1) R plasmid spread (inter- and intraspecies), (2) strain (clonal) dissemination, and (3) transposition of R genes into R plasmids or chromosomes. These many techniques now provide the epidemiologist the means for the rapid identification of many organisms, including the specific strain involved, so that transmission patterns can be followed. Of special interest are the so-called emerging infections, which in the United States include *E. coli* O157:H7 disease, cryptosporidiosis, coccidioidomycosis, multidrug-resistant pneumococcal disease, vancomycin-resistant enterococcal infections, and Hantavirus infections. Special surveillance and diagnostic centers have been established to monitor these infections.[96]

The culture media used will depend on the organisms suspected and whether they are aerobic or anaerobic. Blood agar plates and broth cultures are widely used as a starting point. See individual chapters for specialized media for specific organisms. A useful table indicating the bacteria found by common culture media (and the media used), by type of specimen (urine, respiratory secretions, genital, etc.), and the specialized media needed to detect organisms missed by these standard procedures is available in the appendix of a recent microbiology text.[32]

Once the organism is isolated its antibiotic sensitivity is usually determined and is useful not only in the selection of the proper antibiotic but also in "fingerprinting" the organism for epidemiological tracing. However, this is not necessary for some organisms that are known to be uniformly sensitive to certain antibiotics or that are uniformly resistant to all but one or two antibiotics. In vitro antibiotic testing is not always relevant to a particular infection, especially if the infection is due to mixed organisms. It often does not provide quantitative data or express the effect of an antibiotic on different points in the growth cycle of the organism, and the testing procedure may not include the antibiotic best suited to the clinical situation. The tests must be made on organisms obtained before antibiotic therapy is initiated. Despite these limitations, in vitro antibiotic testing is widely employed and is especially useful for organisms prone to develop antibiotic resistance such as staphylococci, enterobacteria, and *M. tuberculosis*.

The in vitro tests commonly employed are the disk-diffusion techniques in agar and dilution-sensitivity tests on agar plates or in tubes with nutrient broth. The disk procedure is simpler and more rapid, but the zone of inhibition cannot be directly correlated with the concentration of the antibiotic needed to inhibit growth of the organism in vivo. Antibiotic resistance to two antibiotics by disk diffusion does not exclude in vivo effectiveness of the combination; disk diffusion cannot be used for combinations of antibiotics.

The dilution tests provide quantitative data, permitting estimation of the minimum inhibitory concentration of the antibiotic as well as the minimum lethal concentration necessary for killing, which may differ from the minimum inhibitory concentration. The techniques used for dilution tests, however, may vary from laboratory to laboratory; the results are dependent on the size of the inoculum and the broth medium employed. Many laboratories now use automated broth microdilution susceptibility testing, which is rapid and has some economical and procedural advantages over both disk-diffusion and broth macrodilution methods.

As indicated earlier, serological tests have limited application for many bacterial infections. However, they are useful for a number of treponemal, leptospiral, and rickettsial infections. Some of the key tests are indicated in Table 11. Chlamydial infections, including the TWAR strain, are being increasingly recognized as a cause of a variety of clinical syndromes, especially of the respiratory and genital tracts, and microimmunofluorescence tests are available for both IgG and IgM antibodies as well as a genus-specific complement fixation test. Certain levels of titers of antibody are needed to be indicative of recent infection and differentiation between *C. trachomatis* and *C. psittaci* is not possible.

As with viral diagnostic tests, acute and convalescent serum samples should be collected for all bacterial serological tests and the sera tested simultaneously; a fourfold or greater rise in titer is indicative of recent infection. Remember that there is only one time to take the acute-phase sample—in early illness.

For legionellosis, the IgG immunofluorescence titer must reach 1:128 or higher to be significant because of nonspecificity at lower dilutions; similarly, only cold agglutinin titers of 1:64 or higher are regarded as diagnostic of *M. pneumoniae* infection, and even then only about 60% of hospitalized *M. pneumonia* patients are positive, depending on the severity of the infection. The presence of specific IgM antibody is often diagnostic of an acute infection, if demonstrable, as for *B. burgdorferi*, the cause of Lyme disease, but the laboratory diagnosis of this infection is subject to wide variation and standardization of procedures is badly needed. For rickettsial infections, both the organism itself and *Proteus* antigens are useful in serological diagnosis. In streptococcal infections, an increase occurs in a group of antienzyme tests but is too late to be useful diagnostically; a high titer is said to place the person at greater risk of developing rheumatic fever. In syphilis, a great variety of serological tests have been used, employing both nontreponemal and treponemal antigens. The VDRL test is most widely employed as an initial test and is highly sensitive and well standardized but lacks high specificity. The diagnosis can be confirmed by the fluorescent-treponemal-antibody absorption (FTA-Abs)

Table 11. Some Serological Tests Used in Bacteriological Diagnosis

Disease	Test antigen	Test(s)[a]	Comment
Brucellosis	Organism	Agglutination	Four strains
Legionellosis	Organism	IF	Twenty serotypes
Leptospirosis	Organism	Microagglutination, CF, hemolytic, IFA	Crossings occur; many types
Lyme disease	Organism	ELISA IgG, IgM	Needs standardization
Mycoplasma pneumonia	Organism	IF, TRI, CF	
	O rbc	Cold agglutinins	60% positive
Q fever	Organism	CF, agglutination	
Rickettsialpox	Organism	CF	
Rocky Mountain spotted fever	Soluble antigen	CF	
	Proteus strains	Weil Felix	Ox19+++, Ox2+++
		Agglutination	OxKO
Streptococcosis	Extracellular products	Antistreptolysin O, DNase	Confirm past infection
Syphilis	Nontreponemal	VDRL flocculation test	Presumptive
	Treponemal	Rapid reagent tests	Presumptive
		TPI, CF, FTA-ABS	Specific
Yaws	Same as syphilis	Same as syphilis	Cannot differentiate from syphilis
Tularemia	Organism	Agglutination	Often 1:640 or more
Typhoid fever	O antigen	Widal agglutination	≤Fourfold increase

[a]IF, immunofluorescence; CF, complement fixation; IFA, indirect fluorescent antibody; TRI, tetrazolium-reduction inhibition; VDRL, Veneral Disease Research Laboratory; TPI, treponemal immobilization; FTA-ABS, fluorescent-treponemal-antibody absorption.

or hemagglutination (MHA-TP) tests, which are highly specific and available at most state and a few large private laboratories, as well as at the CDC. The *Treponema pallida* immobilization test (TPI) test is a highly specific test but requires maintenance of a mobile, live treponemal antigen; it is available at the CDC. Yaws (*T. pertenue*) shares identical reactivities with *T. pallidum* and cannot be differentiated serologically. Typhoid fever results in increases to the H, O, and other antigens of the organism; an increase in O-antigen titer in the absence of recent immunization is indicative of recent infection. Skin tests may also be useful in diagnosis by demonstration of hypersensitivity to various bacterial antigens. They are commonly employed in tuberculosis, leprosy, nontuberculous mycobacteriosis, brucellosis, and tularemia.

12.4. Interpretation of Tests

The isolation of a bacterial organism from an ill person does not always represent a causal relationship. The organism could reflect (1) part of the normal flora; (2) a healthy carrier state; (3) contamination during the collection process; (4) a transient microorganism contaminating a body surface; (5) a dual or multiple infection, in which the organism isolated is not the one causing the clinical illness; (6) a laboratory error or mix-up; or (7) the true cause of the illness. The factors that point toward a causal relationship are (1) isolation in pure culture or of only one organism; (2) the presence of large numbers of the same organism; (3) the presence of the organism in direct smear from a lesion; (4) procurement from a site normally free of bacteria; (5) repeated isolation of the same organism; (6) demonstration of an immune response; and (7) history of possible recent exposure to the organism in an ill person, in travel, in occupation, or otherwise. The response of the patient to an antibiotic to which the organism is sensitive provides suggestive evidence that the organism caused the disease; but because other organisms are also sensitive to the same antibiotic, this cannot weigh too heavily. Clinical and laboratory judgment plus knowledge of the qualitative and quantitative behavior of human pathogens constitute the best grounds for deciding a causal relationship. It should be remembered that some organisms not usually regarded as pathogenic may cause disease in patients with naturally occurring or drug-induced defects in their immune defenses, or in patients infected with HIV.

On the other hand, the failure to isolate an organism does not exclude a bacterial etiology. Such "false-negatives" could result from (1) prior antibiotic therapy; (2) failure to obtain a specimen from the proper site; (3) collection at the wrong time; (4) a loss of viability during transport to the laboratory; (5) use of inappropriate media, temperature, gaseous

environment, or other conditions for growth of the organism; or (6) failure to hold the culture media for a sufficiently long time, as with certain *Brucella* species. For organisms difficult or impossible to culture, molecular tools such as the polymerase chain reaction are providing important techniques for direct diagnosis, but extremely careful laboratory procedures are needed to avoid cross-contamination and false-positive results.[6]

Serological tests are also subject to misinterpretation. False-positive rises can result from cross-reacting antigens, nonspecific inhibitors, double infection with the other organism causing the illness, and antibody response to vaccination rather than to natural infection. False-negatives, i.e., failure to demonstrate an increase in titer, can occur when the serum specimen is taken too late in illness, two samples are taken too close together to demonstrate a titer rise, the organism is a poor immunogen, the wrong antigen is used in the test, some inhibitor or nonspecificity (as in immunofluorescence tests) obscures a true rise, or the wrong type of test is used for the timing of the serum specimens. Serological tests are also not available for many bacterial infections. One of the common problems is the interpretation of a high IgG antibody titer in a single specimen. The demonstration of IgM-specific antibody is strong but not absolute evidence of a recent infection; it could result from reactivation. The presence of antibody to a rare infection, or to one not usually present in that area as in a returned traveler, or the history of some recent unusual exposure such as in hunting, a new occupation, or a visit from overseas friends also adds weight to the recency of that infection. Such problems are more common in viral and parasitic infections.

13. Proof of Causation

The classic postulates were suggested by Jakob Henle in 1840,[97] some 40 years before bacteria were discovered, and then further developed by his pupil, Robert Koch, in 1884 and 1890, after he had isolated *M. tuberculosis*,[98,99] as well as by Edwin Klebs.[100] A recent book has reviewed the development and subsequent changes in these postulates.[101] The postulates are presented in Table 12. While fulfillment of these postulates provides strong evidence of a causal association, the failure to fulfill them does not exclude this relationship. Even at the time of presentation in 1890, Koch himself recognized some of these limitations, especially the inability to reproduce some diseases in experimental animals. At that time, this was true of cholera, typhoid fever, diphtheria, leprosy, and relapsing fever, for which Koch felt it necessary to fulfill only the first two postulates. Since then, many other limitations have been recognized,[102] as our knowledge of microbiology, epidemiology, and pathogenesis has increased. These include recognition of the asymptomatic carrier state, which would invalidate the second postulate if an individual were carrier of organism A and his disease was caused by organism B. The concepts of multiple causation, of inapparent infection, and of the biological gradient of disease are also limitations. The postulates are not generally applicable to viral and parasitic diseases or for organisms that cannot be grown in culture or induce an immune response. Criteria are also needed for chronic diseases. In an effort to cover these various possibilities, a "unified" set of postulates based mainly on epidemiological criteria have been proposed.[103] It is clear that all postulates and guidelines of causation are limited by the technology available to prove them and by our knowledge of disease mechanisms at the time. The need for establishing guidelines for causation is ever present in the field of bacteriology, where the causal relationship between parasite and disease must be established for newly recognized diseases such as Lyme disease, Legionnaires' disease, Pittsburgh pneumonia, chlamydial pneumonia and urethritis, infant botulism, enterotoxic *E. coli* diarrhea, *H. pylori* and gastric ulcer and carcinoma, toxic shock syndrome, and streptococcal B infections in infancy. New causes for old diseases, new diseases from old causes, and new diseases with new causes keep appearing as our techniques for their isolation and identification improve.

Table 12. Henle–Koch Postulates[a]

1. Parasite occurs in every case of the disease in question and under circumstances that can account for the pathological changes and clinical cause of the disease
2. Occurs in no other disease as fortuitous and nonpathogenic parasite
3. After being fully isolated from the body and repeatedly grown in pure culture can induce the disease anew

[a]From Koch.[98,99]

14. Control and Prevention

The three major principles of control of infectious diseases are as follows: (1) eliminate or contain the sources of infection; (2) interrupt the chain of transmission; and (3) protect the host against infection or disease or both. Additionally, the environment may contribute to the occurrence of disease by its effect on any of the above three areas.

14.1. Environmental Control

The provision of clean and safe air, water, milk, and food; the proper management of sewage and garbage; and the

control of insect vectors of disease are regarded as not only essential to health but also a legal right in most countries. The extent to which they are attained depends on the economy, energy resources, political will, and educational level of the country.

14.1.1. Air. While many infectious agents are airborne on droplet nuclei or particles from infected hosts or environmental sources to susceptible subjects, effective control of this means of transmission has been most difficult to achieve. In open environments, it has been impossible to attain, and even in closed environments attempts to sterilize the air by UV light filtration, propylene glycol, and other chemical aerosols have met with very limited success. At best, control of the air currents generated by air conditioners, water coolers, and fans will help slow down spread of organisms such as *L. pneumophila, M. tuberculosis*, and staphylococci. For patient isolation, laminar-flow units have been effective if properly used. The pollution of air by automobiles and industrial sources does not carry a direct risk of infection, but may depress host defense mechanisms so that disease develops, as in persons with chronic pulmonary diseases.

14.1.2. Water. Improvement in our water supplies has been one of the major factors in the environmental control of infectious diseases, especially of enteric infections such as *Campylobacter*, yersiniosis, cholera, typhoid fever, amebiasis, bacillary dysentery, as well as waterborne viruses like Norwalk viruses. The details of water purification and treatment can be found elsewhere, but involve removal of extraneous materials by filtration, settling, and coagulation, the replenishment of oxygen by aeration, and disinfection by chlorination. Bacteriological and chemical standards for the purity of water have been established and are reinforced by governmental and legal regulations. The presence of *E. coli* in defined numbers per milliliter[2] is taken as an index of fecal contamination of water. However, its absence does not guarantee water safety, since organisms such as hepatitis A and E viruses may escape filtration and chlorination procedures, and more recently *Cryptosporidium* cysts escaped a filtration system in a public water supply in Milwaukee, causing a massive outbreak of diarrhea involving over 403,000 persons.[28] This organism is also resistant to tolerable levels of chlorine. For the traveler, treatment of water with chlorine-release tablets or a drop of Lugal's iodine solution per quart of water 30 min prior to use or by boiling for 5 min (portable heating units can be purchased) will decrease the likelihood of acquiring bacterial intestinal infections in developing countries. Small millipore filter kits are also available for the traveler and are said to remove bacteria, *G. lamblia*, and even some viruses. Should these methods not be available, one can allow the water to run until very hot, collect it, and then use it for drinking water. Bottled water, wine, and beer or other bottled or canned beverages are usually safe.

14.1.3. Sewage and Garbage. Sewage water carries fecal material, industrial and chemical products, and other waste products. It must be safely conveyed without human hazard to septic tanks or to reprocessing, filtration, and activated sludge treatment centers, but has not posed a problem of infectious disease unless cross-contamination with water pipes occurs. The dumping of untreated sewage into streams, rivers, and the open sea is detrimental to fish and marine life and esthetically distasteful and impairs recreational use of such waters. It might result in transmission of certain intestinal pathogens via raw seafood to humans, such as the hepatitis A or E viruses, cholera, or *Cryptosporidium* in water itself. Clams and oysters have been responsible for many outbreaks of this sort, and thorough cooking is needed to kill organisms such as cholera or hepatitis viruses.

The proper disposal of the large amount of garbage, refuse, and other solid waste products produced by our modern society is an increasing challenge to proper land use and modern technology. Direct discharge into the sewage system after grinding and flushing is one method; compactors of garbage and waste material are now available even for home use. If stored and carried elsewhere for disposal, this must be done in closed, stable containers that protect against rats, flies, and other predators. The separation and recycling of certain reusable products such as glass, bottles, paper, and cans is to be encouraged. Large incinerators for burning garbage and refuse provide a safe but energy-expensive procedure. Landfill sites in communities are increasingly scarce, costly as land values increase, and objected to on esthetic grounds. Disposal of radioactive and other toxic wastes generated by medical, industrial, and energy uses in oceans raises international concern about the long-term food and energy potential of oceans, and land or tank disposal, especially of nuclear wastes, is unacceptable to most communities. The increasing uses of pesticides, and domestic and wild animal wastes in streams or rivers that may wash down into public water supplies, pose an increasing threat.

14.1.4. Milk and Food. Milk and food must be protected against contamination at their source, during transport and storage, and in their preparation for consumption. Cows must be free from tuberculosis, brucellosis, and Q fever. The milk must be collected under clean conditions, preferably by

[2]Usually, water is not acceptable for drinking if coliform bacteria exceed 4/100 ml in more than 5% of water samples per month using the membrane-filter technique; samples should be taken at points representative of the distribution system.[104]

automated machines that avoid human contamination, and its quality in the raw state and after pasteurization must meet bacteriological standards.[3] Common pasteurization procedures are heating to 65°C (149°F) for 30 min or the high-temperature or flash method at 72°C (162°F) for 15s. The heat inactivation of the enzyme alkaline phosphatase, normally present in milk, provides the basis for the phosphatase test to ensure proper pasteurization. Before and promptly after pasteurization, milk must be stored and transported at 5–10°C (41–50°F) to storage areas or the consumer. The pasteurization process, even if performed correctly, may not decontaminate some intracellular organisms and those that are cold tolerant, such as *Listeria*. Milk and other food products may contain antibiotics used in treatment of cattle or for growth promotion and pose a hazard to highly sensitive persons.

Our food supplies must also be properly grown, cultivated, stored, and prepared. In developing and tropical areas, vegetables such as lettuce and other products grown in soil enriched by human excreta pose a serious hazard for intestinal infections, and these foods should be avoided by wary travelers. Our modern supermarkets are now selling foodstuffs of all types that have been rapidly imported from other countries and that may carry pathogens. In the summer months, 75% of many fruits and vegetables are harvested outside the country and delivered within days to grocery stores and restaurants in the United States.[105] Salad bars, now present in most restaurants, provide fruits and vegetables that may have originated in Mexico, Central America, or tropical or semitropical climes and are a major source of food poisoning.[106] The fast-food chain, particularly those serving undercooked hamburgers, have been the source of food outbreaks, particularly due to *E. coli* O157:H7 infection in the United States[107]; this organism has also led to an epidemic in a child care center. Foodborne outbreaks have also been due to shigellosis on a commercial airline,[108] and to *Salmonella* in a multistate outbreak due in contaminated cheese.[109] These developments have led to a changing epidemiology of foodborne disease and to new approaches to prevention.[110,111] Human handling during preparation may result in contamination by many bacteria, especially staphylococci, *Salmonella*, and *Shigella*. Thorough cooking immediately prior to eating will reduce the hazard of infection but may fail to inactivate preformed heat-stable toxins such as *C. perfringens*. Proper refrigeration or freezing of food has been as important as water and sewage management in the reduction of intestinal diseases. It prevents the multiplication of most bacteria, and freezing often destroys some parasites such as *Toxoplasma gondii* and *Trichinella spiralis*. However, most organisms or toxins already present at the time of refrigeration or freezing will be preserved in the process and can multiply after thawing and reaching the proper temperature.

[3]Under 200,000 bacteria/ml by standard plate count before pasteurization and under 30,000 bacteria/ml after pasteurization.

14.1.5. Animals and Insect Vectors. Animals provide the source of infection for many of the diseases discussed in this book, such as anthrax, brucellosis, *Campylobacter* infection, leptospirosis, plague, salmonellosis, tularemia, and yersiniosis. The types of exposure differ: some are occupational (anthrax) or avocational (tularemia), some result from common environmental exposures (leptospirosis, salmonellosis), some from close contact with domestic animals (*Campylobacter*), or some from contamination of water sources (*Campylobacter*, yersiniosis) by animals. Knowledge of these potential sources of infection and of appropriate specific measures to avoid or minimize exposure is needed.

Insect vectors may play a passive or active role in transmission of bacterial infections. Passive transfer of the organisms of cholera, salmonellosis, and typhoid fever by flies and other insects may occur but does not seem to be of much epidemiological significance. Good food sanitation, proper storage, and screens are useful to prevent such transfer. The active transport of infection involves multiplication in the insect host. Rickettsial infections are commonly transmitted by insect vectors: *R. rickettsii* of Rocky Mountain spotted fever by wood, dog, and lone star ticks; *R. akari* of rickettsialpox by the mouse mite; and *R. prowazekii* of typhus fevers by the body louse (louse-borne typhus) or rat flea (murine typhus). *B. burgdorferi*, the spirochete that causes Lyme disease, is transmitted by ticks of the *Ixodid* genus, such as *I. dammini*, the deer tick in eastern and midwestern states, and by *I. pacifus* in western states. Ticks may also transmit ehrlichiosis (Sennetsu fever) and babesiosis, and cases have been recognized in the eastern United States.

The control of many of these insect vectors is very difficult, since they exist widely in nature and in many domestic gardens and lawns in endemic areas. Careful protection of the body, especially wearing long pants and high stockings, along with an antitick insecticide in summer months in outside work is important in prevention of tick bites. Intensive searching of the body, as well as domestic pets, after potential exposure is important in preventing Lyme infection, since the tick must remain on the skin some 24 h before it can transmit the organism. Attention should also be directed at the control or avoidance of the dog, rat, mouse, deer, or other animal hosts on which the ticks usually reside. The body louse is controlled by good personal and clothing hygiene and by delousing procedures (heat and chemical treatment).

14.2. Host Factors

The human host may be protected against infection and disease by quarantine or isolation from the sources of infection, by good personal hygiene (especially hand washing), by specific immunization, and by chemoprophylaxis.

14.2.1. Quarantine and Isolation. Quarantine, which began around 1,348 as a 40-day period of keeping suspected plague victims aboard ships or in house quarantine in Venice, has now been rendered largely obsolete by air travel. The WHO now evokes quarantine measures only for plague, yellow fever, and cholera. We rely on surveillance techniques, as discussed in Chapter 2 and by Teutsch,[16] to provide constant monitoring and analysis of infectious diseases and of other conditions of public health importance. The emergence of new and antibiotic-resistant infectious agents[10] has alerted us to the deficiencies in our current surveillance system in the United States,[112] as well as in Europe.[15] A prevention and surveillance strategy has been developed by the CDC for these emerging infections.[96]

Isolation requirement and techniques have also undergone redefinition and reassessment (see Chapter 25 and recent books for details).[113,114] Varying isolation standards in hospitals have been developed for various groups of diseases and often depend on state laws or hospital regulations. Infectious diseases in hospitals have been grouped according to the degree of isolation recommended. Standard precautions are recommended for all patients regardless of their diagnosis. Specific precautions, "transmission-based precautions," are recommended for specific situations. Hand washing remains as a recommendation following any patient contact.

Standard precautions are now legally mandated based on the assumption that the blood and certain body fluids (amniotic fluid, pericardial fluid, peritoneal fluid, pleural fluid, cerebrospinal fluid, semen, vaginal secretions, and any body fluid visibly contaminated with blood) are potentially infected, irrespective of the patient from whom it is derived. With this in mind, the CDC has issued recommendations for the prevention of transmission of HIV, hepatitis B, and other blood-borne pathogens in medical care settings.[115] These standard precautions are to be applied to all patients, including those coming into emergency rooms, where there is often risk of such exposures and the status of the patients is usually unknown. The approach also applies to outpatient settings that involve handling of blood or body fluids. Standard precautions specifically involve the use of gloves whenever contact with blood or other such body fluids is anticipated and other barrier techniques (masks, gowns, and protective eyewear) whenever splashes of such fluids are expected. This would apply to the use of gloves when touching blood and body fluids, mucous membranes, or soiled articles or surfaces, and when doing venipunctures or inserting intravenous lines, and to the use of masks in operative or invasive procedures. The decision to initiate routine HIV testing or testing of high-risk patients and high-risk hospital personnel engaged in invasive or other procedures is left to physicians or individual institutions. If such testing is carried out, the CDC outlines the principles of informed consent and confidentiality involved.[116]

14.2.2. Hygiene. High standards of cleanliness of the individual, the family, the food prepared, and the community contribute to the prevention of infectious diseases. The simple measure of thorough and frequent hand washing is of the highest importance in protecting the individual against pathogens and in interrupting the spread of organisms to others. It plays an essential role in controlling the spread of infection in hospitals and institutions, in restaurants, and in food processing both in industries and at home. The promotion, distribution, and proper use of soap and water for personal hygiene in developing countries need greater emphasis. Its use should decrease enteric and respiratory infections.

14.2.3. Immunization. The specific protection of the individual against infection and disease is the key to modern preventive practice. It may be either passive protection by the transfer of a specific antibody (or antitoxin) from another person or animal immune to it or active immunization through induction of antibody by the organism itself or an antigenic derivative of it. An ideal vaccine closely simulates the protection from natural infection, i.e., it produces good humoral, cellular, and local immunity of long duration. Preferably, it should be better than the short-lived or incomplete immunity found in certain infections such as cholera or shigellosis. It should be in a form of administration and at a cost acceptable to the public. The cost of the vaccine and any side effects should be less than those of the natural disease prevented by it. These ideals are most closely met by well-attenuated live vaccines or antigenic derivatives thereof. The live bacterial vaccines include bacille Calmette–Guérin (BCG) for tuberculosis, a recently developed and licensed oral vaccine (using strain Ty21a) for typhoid fever, and tularemia vaccine. BCG is sparsely used in the United States, and controversy exists about its efficacy (see below). Tularemia vaccine is used in rather small, high-risk groups. Most bacterial vaccines are formalin-, acetone-, or phenolkilled organisms or an antigenic derivative such as the capsular polysaccharides of the meningococcus and pneumococcus (23 types), the toxoids of diphtheria and tetanus, or the protein antigens of *B. anthracis*.

Newer or improved vaccine preparations for many bacterial diseases are under development, testing, or licensure such as those for cholera, *H. influenzae* type b

conjugate (now licensed and used) pertussis, shigellosis, and typhoid fever. The use of conjugated polysaccharide vaccines improves their antigenicity, permitting them to be used in young children.

Someday, timed-release biodegradable polymers may permit pulsed release of vaccines, such as tetanus, thus permitting a single shot to be effective, and avoid the loss now occurring in women and children who do not return to complete the multiple doses required for most killed vaccines. The Institute of Medicine of the U.S. National Academy of Sciences has published a comprehensive evaluation of vaccine priorities for both developed and developing countries based on their feasibility, cost, need, effectiveness, acceptability, side reactions, and other factors.[117]

In developing countries, the WHO's Expanded Program in Immunization is making an enormous effort to vaccinate the young children of the world against six targeted diseases using diphtheria–pertussis–tetanus (DPT), polio, measles, and BCG vaccines, as well as hepatitis B and yellow fever vaccine in some regions. Important progress is being made, and the worldwide coverage in 1996 was approximately 70%. Other organizations are now joining in this effort, as part of a "Child Survival Program," and there is a focus on "growth, oral rehydration therapy, breast feeding, and immunization" (GOBI). The Children's Vaccine Initiative, the organization that manages the technological transition toward new vaccines, has outlined the desired characteristics of such vaccines and has stated that they should be capable of being given orally in the first year of life. In the United States, the recommendation by states that all children be immunized before being allowed into school has greatly expanded coverage in this country. Of the nine diseases against which children are routinely vaccinated, the reported number for five of these and for congenital rubella syndrome was at or near the lowest levels ever.[118] The reported number of these five diseases in 1996 were diphtheria (2 cases), measles (508 cases), poliomyelitis (wild virus—0 cases), rubella (238 cases), and tetanus (36 cases). Only seven cases of congenital rubella syndrome were reported. Measles is a good example of the progress made. After an outbreak of measles between 1989 and 1991 that involved more than 50,000 cases and 11,000 hospitalizations, reported cases declined from 9,643 cases in 1991 to only 281 in 1993.[118,119] Rapid progress is being made in the reduction of meningitis caused by type b *H. influenzae* due to the widespread use of Hib vaccines.

In a survey in 1987, however, serious vaccine deficiencies were found in adults.[120] For example, sero-surveys indicated that 49–66% of persons 60 years or over lacked reliable protective levels of circulating antitoxin against tetanus, and 41–84% lacked adequate protection against diphtheria. Tetanus is a completely preventable disease, and persons over 50 account for 70% of reported cases; thus, special emphasis must be placed on this age group for tetanus boosters, or an initial series if not previously vaccinated. Pneumococcal vaccine is also badly underutilized as indicated by the fact that less than 10% of the higher-risk groups have been vaccinated. A similar lack of protection of our adult population exists against many viral diseases, especially influenza, measles, mumps, rubella, and hepatitis B, as well as pneumonia. Today, some 50,000–70,000 adults die each year of influenza, pneumococcal infections, and hepatitis B, with a cost to society of these and other vaccine-preventable diseases of adults exceeding 10 billion dollars each year.[121] Detailed recommendations have been issued to improve this situation[121] and a call for action issued by the CDC.[122]

Recommendations for the immunization of persons with altered immunocompetence, such as AIDS, have been made by the Advisory Committee on Immunization Practice (ACIP). In general, live viral or bacterial vaccines are contraindicated in persons with severe immunodeficiency due to any cause, including HIV-infected persons. However, evaluation and testing for HIV infection of asymptomatic persons are not necessary before administering measles–mumps–rubella (MMR) vaccine, since no documented serious adverse reactions have been noted in either asymptomatic or symptomatic persons infected with HIV. Thus, MMR vaccine is recommended for both adults and children when otherwise indicated, regardless of HIV status. Enhanced, inactivated poliomyelitis vaccine is preferred in HIV-infected persons, as is pneumococcal vaccine of these persons over age 2 years. HIV-infected children under 2 years should receive Hib vaccine according to the routine schedules. Both HIV-infected children may have suboptimal immune responses to such vaccines. Recent studies suggest, however, that the benefits of measles, mumps, and rubella vaccines outweigh the risks to children with AIDS, at least in developing countries. It should be noted that in developing countries where the risks of exposure are higher, greater use of live vaccines is recommended. The WHO thus recommends use of standard Expanded Programme on Immunization (EPI) vaccines in persons with symptomatic or asymptomatic HIV infections,[123] but suggests that inactivated poliomyelitis vaccine (IPV) be considered as an alternative to oral polio vaccine (OPV). Some complications have arisen with BCG vaccine in such immunosuppressed children, and its use should be suspended in unimmunized individuals with symptomatic AIDS in countries where the other targeted diseases remain serious risks; in asymptomatic HIV-infected individuals in areas where the risk of tuberculosis is high, BCG is recommended at birth or soon thereafter. Guidelines should be consulted for updated recommendations, as data are often

incomplete. Separate needles are required to avoid the possibility of parenteral transmission of HIV (and hepatitis B virus). The jet gun should not be used in immunization programs, except in an epidemic emergency, until further data are available on the possible risks associated with its use.

Table 13[124] gives the current recommended schedule for active vaccination of infants and children. Standards for pediatric immunization have also been issued by the same committee.[125] Information for international travelers,[126] as well as the uses and limitations of each vaccine, will be found in the appropriate chapters of this book. A brief summary follows.

14.2.3.1. Anthrax. No confirmed cases reported in the United States since 1988. The vaccine is distributed only by the Division of Biologics, Michigan Department of Public Health, and is intended only for high-risk occupational exposures, such as persons working with imported goat hair, wool, and hides (sheep and goats) and laboratory workers regularly exposed to this organism. The vaccine is a killed cell-free culture filtrate prepared from the protective antigen. A recent review of anthrax is available.[127] (See also Chapter 4.)

14.2.3.2. Botulism. There are three forms: classical, infant, and wound; a total of 119 cases were reported in 1996. Passive immunization is available consisting of horse serum with anti-A, B, and E toxins and used for persons strongly suspected of botulism or when disease is first diagnosed. Trivalent antitoxin is available from the CDC in Atlanta.

Table 13. Recommended Childhood Immunization Schedule, United States, 1997[a]

	Age										
Vaccine	Birth	1 mo	2 mos	4 mos	6 mos	12 mos	15 mos	18 mos	4–6 yrs	11–12 yrs	14–16 yrs
Hepatitis B[b,c]	Hep B-1		Hep B-2		Hep B-3					*Hep B*[c]	
Diphtheria, and tetanus toxoids and acellular pertussis[d]			DTap or DTP	DTap or DTP	DTap or DTP		DTap or DTP		DTap or DTP	Td	
Haemophilus influenzae type b[e]			Hib	Hib	Hib	Hib					
Poliovirus[f]			Polio[f]	Polio			Polio		Polio		
Measles, mumps, rubella[g]						MMR			MMR or MMR		
Varicella virus[h]							Var			***Var***	

[a]This schedule indicates the recommended age for routine administration of currently licensed childhood vaccines. Some combination vaccines are available and may be used whenever administration of all components of the vaccine is indicated. Providers should consult the manufactures' package inserts for detailed recommendations. Vaccines are listed under the routinely recommended ages. Bars indicate range of acceptable ages for vaccination. Shaded bars indicate catch-up vaccination: at 11–12 years, hepatitis B vaccine should be administered to children not previously vaccinated, and varicella virus vaccine should be administered to unvaccinated children who lack a reliable history of chickenpox. Use of trade names and commerical sources is for identification only and does not imply endorsement by the Public Health Service or the U.S. Department of Health and Human Services. Source: Advisory Committee on Immunization Practices (ACIP), American Academy of Pediatrics (AAP), and American Academy of Family Physicians (AAFP).

[b]*Infants born to hepatitis B surface antigen (HBsAg)-negative mothers* should receive 2.5 μg of Merck vaccine (Recombivax HB®) or 10 μg of SmithKline Beecham (SB) vaccine (Energix-B®). The second dose should be administered >1 month after the first dose. *Infants born to HBsAg-positive mothers* should receive 0.5 ml hepatitis B immune globulin (HBIG) within 12 h of birth and either 5 μg of Merck vaccine (Recombivax HB®) or 10 μg of SB vaccine (Engerix-B®) at a separate site. The second dose is recommended at age 1–2 months and the third dose at age 6 months. *Infants born to mothers whose HBsAg status is unknown* should receive either 5 μg of Merck vaccine (Recombivax HB®) or 10 μg of SB vaccine (Engerix-B®) within 12 h of birth. The second dose of vaccine is recommended at age 1 month and the third dose at age 6 months. Blood should be drawn at the time of delivery to determine the mother's HBsAg status; if it is positive, the infant should receive HBIG as soon as possible (no later than age 1 week). The dosage and timing of subsequent vaccine doses should be based on the mother's HBsAg status.

[c]Children and adolescents who have not been vaccinated against hepatitis B during infancy may begin the series during any childhood visit. Those who have not previously received three doses of hepatitis B vaccine should initiate or complete the series at age 11–12 years. The second dose should be administered at least 1 month after the first dose, and the third dose should be administered at least 4 months after the first dose and at least 2 months after the second dose.

[d]Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) is the preferred vaccine for all doses in the vaccination series, including completion of the series in children who have received one or more doses of whole-cell diphtheria and tetanus toxoids and pertussis vaccine (DTP). Whole-cell DPT is an acceptable alternative to DTaP. The fourth dose of DTaP may be administered as early as 12 months of age, provided 6 months have elapsed since the third dose and if the child is considered unlikely to return at age 15–18 months. Tetanus and diphtheria toxoids (Td), absorbed, for adult use, are recommended at age 11–12 years if at least 5 years have elapsed since the last dose of DTP, DTaP, or diphtheria and tetanus toxoids. Subsequent routine Td boosters are recommended every 10 years.

[e]Three *H. influenzae* type b (Hib) conjugate vaccines are licensed for infant use. If PRP-OMP (PedvaxHIB® [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required. After completing the primary series, any Hib conjugate vaccine may be used as a booster.

[f]Two poliovirus vaccines are currently licensed in the United States: inactivated poliovirus vaccine (IPV) and oral poliovirus vaccine (OPV). The following schedules are all acceptable by ACIP, AAP, and AAFP, and parents and providers may choose among them: (1) IPV at ages 2 and 4 months and OPV at age 12–18 months and at age 4–6 years; (2) IPV at ages 2, 4, and 12–18 months and at age 4–6 years; and (3) OPV at ages 2, 4, and 6–18 months and at age 4–6 years. ACIP routinely recommends schedule 1. IPV is the only poliovirus vaccine recommended for immunocompromised persons and their household contacts.

[g]The second dose of measles–mumps–rubella vaccine is routinely recommended at age 4–6 years or at age 11–12 years but may be administered during any visit, provided at least 1 month has elapsed since receipt of the first dose and that both doses are administered at or after age 12 months.

[h]Susceptible children may receive varicella vaccine (Var) during any visit after the first birthday, and unvaccinated persons who lack a reliable history of chickenpox should be vaccinated at11–12 years. Susceptible persons aged≥13 years should receive two doses at least 1 month apart.

There is a 10–15% risk of adverse reactions (anaphylaxis, serum sickness). Botulism toxoid is also available and effective, but because of the rarity of the intoxication, it is recommended only for laboratory workers and others working directly with the toxin. It can be obtained from the CDC. (See also Chapter 6.)

14.2.3.3. Cholera. The available inactivated vaccine offers rather poor protection (about 50%) over a short period (3–6 months); the transmission of infection is not prevented. No country or territory currently requires immunization for entry.[126] However, local authorities may require it, and one dose satisfies such regulations and is valid for 6 months. For persons highly exposed in highly endemic areas, a three-dose primary series is given 1 week to 1 month apart and a booster dose every 6 months. The vaccine is probably not effective against the newly discovered *V. cholera* 039 strain. A number of oral cholera vaccines are under development and testing, some of which contain the *V. cholera* 039-Bengal strain.

14.2.3.4. Diphtheria–Pertussis–Tetanus (DPT) Vaccine (see Table 13). Routine primary immunization with DPT vaccine is given at 2, 4, and 6 months with a fourth dose at 15 months and a booster at 4–6 years before entry into school.[124] Some 20% of adults or more may be unprotected against diphtheria and need either a full primary series or a booster dose of a preparation for adults or children >7 years old (Td). Booster doses of Td are suggested for all adults every 10 years.[121] Local Arthus-type reactions and sometimes systemic immune complex reactions (serum sickness) may occur in hyperimmunized adults. These may be attended by severe head, muscle, and joint aches and fever of about 24 h duration. Corticosteroids may be given orally over 3–5 days, for symptomatic relief. Diphtheria antitoxin should be given to asymptomatic, unimmunized contacts in whom close surveillance is not possible, plus penicillin (600,000 U of the benzathine form or, if sensitive, a 7-day course of erythromycin) and injection of diphtheria toxoid. If close surveillance is possible, the antitoxin can be omitted.

14.2.3.5. Haemophilus influenzae Type b Vaccine (Hib). This infection is an important cause of meningitis in children, particularly those under the age of 5 years, and is now being recognized as important in older persons whose immunity has waned. Two forms of conjugated vaccines are available, and two in combination with DPT. They are given at 2, 4, and 6 months with DPT and OPV and again at 12–15 months when MMR is given. One preparation (PRP–OMP) is not given at 6 months (see Table 13 on routine active vaccination of infants and children). (See also Chapter 16.)

14.2.3.6. Meningococcal Infections. Meningococcal infections can result in epidemics but, in U.S. civilians, most commonly occur as single cases or localized clusters, with a third of the cases occurring in persons 20 years of age or over. Two polysaccharide vaccines are currently available in the United States: a bivalent A-C and a quadrivalent vaccine containing A, C, Y, and W-135 polysaccharides. A single dose of either is adequate to induce serospecific immunity.[32] Routine vaccination is not recommended in the United States because of the relatively low risk of infection and because a good group B antigen is not available. Vaccine usage is recommended as an adjunct to antibiotic chemoprophylaxis for household and other close contacts of persons with meningococcal disease due to serotypes A, C, Y, and W-135. The quadrivalent vaccine is recommended for travelers to endemic areas. The duration of protection is unclear. Side reactions are infrequent and mild, but the safety for pregnant women has not been established. Because of the high risk in military recruits, they have received meningococcal vaccine on entering the services since the early 1970s. Currently, they receive groups A, C, Y, and W-135. (See also Chapter 23.)

14.2.3.7. Plague. The vaccine consists of formalin-inactivated organisms; its efficacy has not been critically evaluated. It should be given only to high-risk groups such as field and laboratory personnel exposed to the organism and possibly to workers in plague enzootic or endemic rural areas where avoidance of rodents, fleas, and wild rabbits is not feasible (agricultural advisors, Peace Corps volunteers, or military personnel on maneuvers).[24] The schedule consists of five injections, with dosage varying with age. In the face of continued exposure, single booster doses at about 6-month intervals are given for two doses, then at 1- to 2-year intervals. Local reactions are common, sterile abscesses are rare, and systemic reactions (fever, headache, and malaise) may occur on repeated injections. (See also Chapter 27.)

14.2.3.8. Pneumococcal Infections. The estimated annual incidence of pneumococcal pneumonia in the United States is 68–260 cases per 100,000 population and of bacteremia is 7–25 per 100,000. Mortality is highest in patients with bacteremia, meningitis, underlying medical conditions, and those over 60 years of age. The currently available pneumococcal polysaccharide vaccine contains purified capsular materials from 23 types of *S. pneumoniae*, which together account for 87% of recent bacteremic pneumonia in the United States. The vaccine is particularly recommended for three groups: (1) adults with chronic diseases, especially of the cardiovascular or pulmonary systems; (2) adults with chronic illnesses specifically associated with an increased risk of pneumococcal infection or its complications (splenic dysfunction, Hodgkin's disease, multiple myeloma, cirrhosis, alcoholism, renal failure, CSF leaks, and in immunosuppressed patients); and (3) older adults, especially those 65 years of age and over, regardless of whether they are healthy or diseased. Vaccination is recommended

for hospitalized patients in these high-risk groups before discharge. A single dose is recommended without a booster. Mild side reactions consisting of erythema and pain at the site of injection occur in about half the recipients. Medicare helps pay the cost in these designated groups. Pneumococcal infections are also a problem in young children in developing countries, so that there is increasing interest in the use of the vaccine in these groups. (See also Chapter 28.)

14.2.3.9. Tetanus. See DPT (see Section 14.2.3d) for routine immunization. For wound management, tetanus–diphtheria (Td) adult-type, or tetanus toxoid (TT) only, is used alone or in combination with tetanus immune globulin (TIG) in doses of 250 U (in separate site and syringe), depending on the severity of the wound and the history of prior immunization. Moderate to severe local and systemic reactions may occur in some hyperimmune adults receiving booster doses or for wound prophylaxis. (See also Chapter 37.)

14.2.3.10. Tuberculosis. This disease remains the most important cause of death in the world due to an infectious agent. It is a major killer of individuals in persons aged 20–30 years. In 1994, the WHO declared this disease to be a public health emergency,[128] and it is believed to be "out of control" in many parts of the world. The WHO identified 10 industrial countries in which cases of tuberculosis increased 5–33% in recent years. In the United States, an estimated 15 million persons are believed to be infected. The increase of infection in HIV-infected persons with the emergence of multidrug-resistant strains in this group and in others who were inadequately treated is of special concern. Such resistant strains spread readily to others. About 4.5% of tuberculosis in the United States was associated with HIV infection, and a rise to 13.8% is anticipated by the year 2000. As Comstock[129] has pointed out, the patterns of change and reasons for it are multiple and complex both in the United States and other areas of the world. While HIV is widely blamed, there are many other factors such as migration, poverty, malnutrition, and decreased tuberculosis control efforts, and it is difficult to assess the relative importance of each in the trends observed. In 1991, 56% of active cases were reported among Hispanics and African Americans. The only vaccine available is BCG, and contradictory evidence exists as to its efficacy. An excellent brief review has recently summarized the evidence.[130] More people have received BCG vaccine than any other vaccine, yet its efficacy remains in doubt. It is a part of the routine WHO EPI program. For example, the WHO estimates that 85% of all children born in 1990 received BCG vaccine in their first year of life. Estimates of its efficacy range from 0 to 80% in different settings. Such great variation has been attributed to different vaccine strains, methodological differences, variation in the infecting organism in different countries, the genetic background of the exposed groups, and environmental interactions with other mycobacterial strains in the population. Indeed, a higher efficacy has been seen against leprosy than tuberculosis in some studies. One recent meta-analysis involving 14 trials and 12 observational studies concluded that BCG reduced the risk of tuberculosis by 50%,[131] despite great heterogeneity in the data. In another meta-analysis of results showing homogeneity, BCG was 86% effective against miliary tuberculosis and tuberculous meningitis; the preventive effect against pulmonary tuberculosis showed such heterogeneity that they did not calculate a summary measure.[132] It seems reasonable to believe that BCG is effective against the spread of tuberculosis within the body, such as miliary spread and spread to the meninges, but that its protection against infection varies greatly in different settings and with different vaccines. Comstock[129] has discussed the use of BCG and the CDC has outlined its use in control in a joint statement with the ACIP and the Advisory Committee on the Control of Tuberculosis.[133] General problems in the production standards for BCG and the need for recombinant technology in the development of a vaccine whose mechanism of action and efficacy can be better understood and evaluated have been recently presented.[134–136] BCG use is not routinely recommended in the United States because of the generally low incidence of disease and because BCG interferes with the interpretation of the tuberculin skin test. These recommendations may have to be modified for high-risk groups, in view of recent increases in incidence and resistant organisms. (See also Chapter 39.)

14.2.3.11. Typhoid. Not recommended for routine use in the United States or for international travel except for areas where there is a recognized risk of exposure to *Salmonella typhi*. It is recommended for travelers who will have prolonged exposure to potentially contaminated food and water in smaller cities or villages in rural areas in Africa, Asia, and Central and South America. An oral, live attenuated vaccine is licensed containing the Ty21a strain. It is taken in an enteric-coated capsule on alternate days for four doses, with a booster dose every 5 years if exposure continues.[137] An inactivated parenteral vaccine is also available and soon a Vi capsular polysaccharide vaccine will be available. Few reactions are due to the oral vaccine, but local and systemic reactions lasting 1–2 days are common with the inactivated parenteral vaccine. (See also Chapter 42.)

14.2.4. Antibiotic Prophylaxis. The success of preventing natural infection or disease or both with antibiotic prophylaxis depends on the sensitivity of the organism to the drug employed, whether single or multiple bacterial species are involved, the timing of administration in relation to infection, and the ability of the drug to reach effective concentrations in body sites before the organism is present. It has

Table 14. Prophylactic Uses of Antibiotics

Condition	Chapter (section) in this volume	Persons at risk	Antibiotic	Dose/time
Diphtheria	13(9)	Carriers of toxigenic strains	Penicillin or erythromycin	Full dose over 7–10 days
Gonorrhea	15(9)	Persons sexually exposed to infection	Penicillin	Full dosage as for treatment
Meningococcal meningitis	23(9)	Intimate contacts of cases or in closed outbreaks	Sulfadiazene for sensitive organisms	1 g adults or 0.5 g children q 12 h × 4 doses
			Rifampin	10 mg/kg per day for 4 days
Strep and rheumatic fever	34(9)	Rheumatic heart disease patients (prevention of rheumatic fever)	Penicillin (benzathine), i.m.	1.2 million U/mo
		Sometimes family contacts of strep cases	Penicillin, oral	200,000–250,000 U daily
Surgical infections	25(9.2.8)	Certain surgical patients[a]	Dependent on site of operation	
Syphilis	35(9)	Known exposures ("epidemiological treatment")	Penicillin	Same as treatment
Tuberculosis	39(9.3)	Recent skin test positive Contacts of cases Healed Tb patients; never treated Tb cases	INH	Adults 5 mg/kg per day for 12 mo

[a]C-V, C-section and vaginal hysterectomy, prophylactic hip, certain intestinal, biliary, CNS.

been employed in persons at high risk after known exposure in epidemics (meningococcus), in household contacts of cases (e.g., streptococcus, meningococcus, tuberculosis), and in sexual partners (gonococcus, syphilis), one of whom is infected. It has been employed after infection is diagnosed to prevent further spread or to limit complications (tuberculosis, rheumatic fever) or to limit the duration of the carrier state. The major limitations have been the development of antibiotic resistance, multiple organisms causing the disease, and poor patient compliance for long-term prophylaxis. Any mass prophylactic program aimed at a large group, especially a closed population, over a long term sets the stage for the development of resistance in the organism of interest as well as other circulating organisms. Antibiotic prophylaxis has met with debatable success when the bacterial sensitivity is not high, if the antibiotic is inhibitory but not bactericidal, if multiple organisms are involved (especially gram-negative), and if the risk of infection is relatively low, as in clean surgical operations. For greater detail, see books on clinical infectious diseases[38] or reviews on antibiotic usage,[138] as well as specific chapters in this book.

Table 14 lists some uses of antibiotic prophylaxis. The most successful are the prevention of recurrent streptococcal infections in persons with rheumatic heart disease and the prevention of disease in persons with infections due to *M. tuberculosis*, especially recent infections. Antibiotic prophylaxis with sulfadiazine for sulfa-sensitive organisms or rifampin for sulfa-resistant organisms is advocated for family or close contacts of patients with meningococcal meningitis or outbreaks in closed settings. These principles apply in large community outbreaks when sulfadiazine is given on a mass basis for sulfonamide-sensitive meningococci; of resistant strains in this situation, rifampin is not recommended because of the possibility of developing resistance to this drug.[17] "Epidemiological treatment" after known sexual exposure to gonorrhea or syphilis is effective, but requires a full therapeutic regimen. Prevention of infection during and after surgery is advocated in surgical procedures at high risk to infection such as total hip and knee replacement, colon–rectal surgery, and transurethral resection of the prostate.[139] Patients whose immune status is compromised by steroids, irradiation, alkylating and antimetabolic agents, and other immunosuppressive drugs are at high risk to certain bacterial, fungal, and viral organisms, including some that are not normally pathogenic, but no antimicrobial prophylaxis has been effective. They may be placed in protective isolation (see Section 14.2.1) and closely watched and antibiotic therapy instituted if infection occurs. A possible exception to the ineffectiveness of antibiotics in preventing infections is the prophylactic use of isoniazid in immunosuppressed patients with inactive tuberculosis. Antibiotics or other prophylactic measures for prevention of traveler's diarrhea are recommended only for the long-term traveler in high-risk endemic areas[80,106]; for short-term visitors, bismuth subsalicylate has proved useful.[43]

CHAPTER 2

Public Health Surveillance

Philip S. Brachman

1. Introduction

The term *surveillance*, derived from the French word meaning "to watch over," may be defined as a system providing close observation of all aspects of the occurrence and distribution of a given disease through the systematic collection, tabulation, analysis, and dissemination of all relevant data pertaining to that disease.[1] The preferred term is *public health surveillance*, which emphasizes the focus of surveillance as discussed in this chapter to develop data that results in a public health preventive act ion. This distinguishes public health surveillance from other types of surveillance.[2] Although the methodology of surveillance is basically descriptive, its function is more than merely collective and archival. Surveillance must be dynamic, current, purposeful, and result in a public health action. This action frequently results in the establishment of a new or the reinforcement of an existing public health policy. It is fundamental for the prompt and effective control and prevention of disease. Traditionally, surveillance was first applied to the acute communicable diseases in the mid-1800s.[3] Since then, surveillance methodologies have been utilized to cover a many infectious diseases,[1] a wide variety of non-infectious diseases, and other health-related events such as environmental hazards, potential bioterrorism events injuries, vaccinations, the distribution of biological products, and health-care delivery.

2. History

William Farr, of the General Registrar's Office of England and Wales, is credited with initiating disease surveillance in the mid-1800s though mortality and some morbidity data were being collected during previous years in communities in other countries. He collected, collated, and analyzed vital statistical data and distributed reports to appropriate health personnel as well as to the public.[3] In the United States, the collection of national morbidity data was initiated in 1878, when Congress authorized the Public Health Service (PHS) to collect reports of the occurrence of the quarantinable diseases, namely, cholera, plague, smallpox, and yellow fever. In 1893, Congress passed an act stating that weekly health information should be collected from all state and municipal authorities. In 1902, in an attempt to develop uniformity, the Surgeon General of the PHS was directed to provide forms for collecting, compiling, and publishing surveillance data. In 1913, the state and territorial health authorities recommended that every state send weekly telegraphic summaries reporting the occurrence of selected diseases to the PHS. All states were reporting the occurrences of diseases by 1925. In 1949, when the National Office of Vital Statistics (NOVS) was established in the PHS, the communicable-disease-reporting function (morbidity reporting) was merged with the national mortality registration and reporting functions that were the primary responsibility of the NOVS. Until the early 1950s, the communicable disease reports were published weekly in the official journal *Public Health Reports*. When this journal became a monthly publication, the NOVS issued a separate weekly bulletin, the *Morbidity and Mortality Weekly Report* (MMWR), that was distributed to state health officers, state epidemiologists, county and city health officers, and others including persons who requested its receipt. In January 1961, the responsibility for receiving morbidity reports from the states and larger cities and issuing of the MMWR was transferred from Washington, DC, to the Communicable Disease Center [now called the Centers for Disease Control and Prevention (CDC)] in Atlanta, Georgia.

In the United States, the application of the term *surveillance* to the watchfulness over a nationally important communicable disease (malaria) was begun in 1946 by the CDC[4] in part to monitor veterans who were returning from endemic areas. The benefit of applying a specific case definition and a critical epidemiological evaluation to the former rather than crude resulted in the recognition that malaria had ceased to be an indigenous disease. Endemic spread of infection had ceased some years before through control of the vector.

In 1955, following the initial introduction of the Salk, killed poliomyelitis vaccine, an epidemic of vaccine-associated poliomyelitis occurred ("Cutter Incedent"). The case was traced to one manufacturer's faulty manufacturing process. Subsequently, national surveillance of poliomyelitis was ordered by the Surgeon General as an essential step toward a solution for this national disaster.[5] In 1957, influenza was placed under surveillance in anticipation of the impending pandemic of Asian influenza for which a comprehensive national program of widespread vaccination and education of doctors and preparation of hospitals to meet such a possible disaster was undertaken by the Surgeon General. The influenza surveillance program has continued, and one of its essential functions is to provide information to guide manufacturers in the preparation of influenza vaccine as concerns its antigenic composition and the amount of vaccine to produce. In 1961, because of the increasing public health concern with salmonellosis, a special *Salmonella* surveillance program was developed in conjunction with the states to better define the problem so that appropriate control and prevention measures could be instituted. In recent years, surveillance has been extended to HIV, Lyme Disease, West Nile virus infection, SARS, avian influenza and many other public health illnesses or conditions.

The CDC has published a series of reports that further define public health surveillance. These include an outline of a comprehensive program,[6] "Guidelines for Evaluating Surveillance Systems,"[7] and "Case Definitions for Public Health Surveillance."[8] Responding to the reality of new emerging infections and reemerging infections, a number of surveillance systems have been implemented to define these diseases supported by CDC and other groups. Responding to reality, new surveillance systems are being developed and evaluated related to public health preparedness for noting as early as possible natural and man made disasters. There are several textbooks that have been published on public health surveillance (see Suggested Readings).

At present, the occurrence of 59 diseases is reported weekly and that of 7 other diseases are reported annually by state health departments to the CDC. Seven additional diseases are reported by either special case-reporting forms or line-listing forms submitted either monthly or annually. These reports are published in the MMWR and are summarized annually in the *MMWR Annual Summary*.[10] These lists are reviewed annually by the state and territorial epidemiologists and modified as indicated by the changing nature of the diseases and the occurrence of new diseases. Additionally, more intensive surveillance is maintained over selected diseases by means of special surveillance efforts to develop more specific data concerning these diseases. Selected non-infectious diseases are also under surveillance, such as birth defects, non infectious injuries, and diabetes mellitus.

National disease surveillance programs are maintained by most countries in the world. The methods used to report cases, the diseases to be reported, the analyses, and the type and frequency of reports vary, but the value and importance of surveillance is universally recognized. A number of European countries have been working to improve national surveillance programs and develop an European reporting system.[11] Desenclos has discussed various methods for collecting surveillance data.[12] The World Health Organization (WHO) maintains surveillance on the quarantinable diseases (cholera, plague, and yellow fever) as well as other selected diseases. The most recent disease to come under worldwide surveillance is acquired immunodeficiency syndrome (AIDS). WHO prepares weekly reports as well as other reports summarizing these data. WHO also responds to worldwide disease problems by developing special surveillance programs for emerging infections (i.e., Nipal virus, SARS) or for potential pandemic diseases (i.e., avain influenza).

3. Use of Surveillance

A surveillance program can be designed to produce a variety of output data depending on the purpose of the program. It can portray the natural history of the disease, including a description of the occurrence of the disease by time, place, and person. Surveillance data should describe the background (sporadic, endemic, or ongoing) level of the disease, as well as changes in the occurrence of the disease as modified by nonrecurring events such as epidemics. Surveillance can be used to monitor changes in the agent, such as antibiotic resistance in gonococci, staphylococci, pneumococci, and *Mycobacterium tuberculosis*, or changes in virulence, or genetic changes.

Analysis of surveillance data can help to establish priorities for developing a disease-specific control and/or a prevention program. Surveillance can also be used to confirm a hypothesis about the occurrence or distribution of

disease or indicate the need for further study or additional data. Analysis of surveillance data can lead to the development and/or institution of control and/or prevention measures such as chemotherapy, chemoprophylaxis, new resources or resource allocation (e.g., people, equipment, or monies), or additional training for persons involved in control and prevention activities. Surveillance can be used to evaluate the effectiveness of newly instituted control and/or prevention measures. Surveillance data are also important in forecasting or predicting the future pattern of the occurrence of a disease.

In this chapter, surveillance is discussed primarily as it involves bacterial infectious diseases. Surveillance techniques for other infectious diseases are similar, though there may be some variation in the data collection procedures.

4. Data Sources

The WHO in 1968 codified the term *surveillance* on a truly global basis.[13] Ten "elements" or distinguishable sources of data were identified Any one or any combination of the ten can be used to support a disease-specific surveillance program. The sources used to develop the surveillance data depend on the disease itself, the methods used for identifying the disease, the goals of the program, the personnel and material resources available, the population involved, and the characteristics of the disease's occurrence. One source of data can be used regularly and other methods utilized as necessary to improve the sensitivity and/or specificity of the data depicting the occurrence of the disease.

4.1. Mortality Data

Mortality registration has been used the longest, but it is useful only for diseases that are associated with fatalities. If the case-fatality ratio is too low, mortality statistics may not provide an accurate assessment of the occurrence of the disease. If mortality rate data are accurate and if the proportion of deaths to cases is known from past studies, then the number of deaths can provide an estimate of the actual number of cases that have occurred and define the pattern of disease occurrence over time.

Unfortunately, there is wide variation in the accuracy with which death certificates are filled out. Diagnoses are not defined consistently and diseases under surveillance may not be recorded even if they were a contributory cause of death, Also, there is a time lag in reporting deaths, so that a surveillance program based on mortality registration has an inherent delay of from weeks to months. In general, information derived from analyses of the cause of death on death certificates is inconsistent and likely inaccurate.

An example of the use of mortality data for surveillance is the collection of pneumonia and influenza weekly mortality reports from 122 American cities.[14] These data are used to describe weekly pneumonia and influenza activity and help determine the burden and geographic distribution of disease. Another example occurred in the 1960s during an investigation of shigellosis in rural areas in Central America where there was no ongoing surveillance program.[15] The only available reports of any of the cases were listings of deaths that were routinely noted in "vital statistics" books maintained in the communities. By noting the recording of deaths and by knowing the case-fatality ratio, it was possible to develop information concerning the occurrence of cases of shigellosis.

4.2. Morbidity Data

The second, and most commonly used, source of surveillance data is morbidity or case reporting. This is a prompt, simple, and useful system that is dependent on the reporting of cases of the diseases under surveillance. Reporting the occurrence of disease is the responsibility of the patient's health-care professional, usually a physician. He or she may delegate this responsibility to someone else such as a nurse, clerk, or administrator. Cases may be reported by the responsible person calling the health department or vice versa, or they may be reported each day or each week on a special form sent by mail or fax. Computers are also increasingly being used to report cases at all levels of reporting. Alternatively certain diseases lend themselves to mandatory reporting of laboratory results by laboratories, if the disease under surveillance requires a laboratory test for diagnosis. The techniques of reporting are described in greater detail in Section 6.

4.3. Individual Case Reports

Individual case investigation is more likely to be performed with rare diseases or unusual cases of a common disease. For diseases of high frequency, investigating individual cases is usually neither practical nor necessary, but may be conducted in order to obtain more specific case data or as a check on the validity of morbidity or mortality reporting. As a disease decreases in incidence, individual case investigation may be of increasing importance to determine why the case occurred and to further direct control and prevention measures. As the occurrence of a disease decreases, leading toward prevention, elimination, or eradication status, then intensive investigation of each reported case is important. The value of this approach was dramatically demonstrated

in the smallpox eradication program[13] and is currently being practiced in the international poliomyelitis eradication program.[16] Additionally, as measles immunization activities are being intensified in the United States, individual case reporting is being emphasized.[17]

4.4. Epidemic Reporting

The fourth source of surveillance data is the reporting of epidemics. Frequently, there is quantitative improvement of reporting when clusters of cases occur. Thus, single cases of shigellosis or salmonellosis may not be individually reported, but if there is an epidemic, then all cases that are part of the epidemic may be reported.

4.5. Epidemic Field Investigation

Epidemic field investigations may uncover more cases of the disease than would have been reported without the investigation. In the epidemic of salmonellosis in Riverside, California, in 1965, several hundred cases were initially reported; however, following a field investigation, 16,000 cases were estimated to have occurred.[18] In 1987, an epidemic of *Salmonella typhimurium* gastroenteritis occurred in Chicago, Illinois, related to pasteurized milk and 16,000 cases were cultured positive for the organism. However, community surveys suggested that between 170,000 and 200,000 cases occurred.[19] In 1993, cases of cryptosporidiosis were reported from Milwaukee, Wisconsin. Contaminated, inadequately purified city water was shown to be the source of infections. Subsequently, investigations suggested that more than 400,000 cases had occurred. The decision to investigate an epidemic will be based on the specific disease, the seriousness of the outbreak, the extent of the problem, the anticipated need for more specific information concerning the occurrence of the epidemic, availability of resources, research potential, and possibly political pressures.

4.6. Laboratory Reporting

The laboratory is essential in identifying and confirming pathogens. Although many diseases can be adequately described clinically, there are others for which laboratory identification of the etiologic agent is essential for accuracy. For example, gastroenteritis may be caused by various organisms; but it is frequently not possible to be certain of the etiology on the basis of clinical and epidemiological data alone. Thus it is necessary to perform laboratory testing to identify the etiologic agent. The accuracy of the *Salmonella* and *Shigella* surveillance programs in the United States depends on laboratory testing. Every state now has laws that identification of agents of reportable infectious diseases must be reported to the local health authorities.

In addition to disease identification, the laboratory can also provide important information concerning specific characteristics of microorganisms that are epidemiologically important. For example, the antigenic characteristics of influenza strains are important, since significant changes in the prevalent strain will necessitate changes in formulation of vaccine to be used before the next influenza season. An example is the surveillance of avian influenza strains isolated from avians and humans to identify genetic changes that will increase the likelihood of human-to-human transmission. Identifying the serotype of salmonellae isolated from different patients may be necessary in order to associate different isolates as part of a single epidemic and to identify the source of infection. Careful attention to antibiotic sensitivity patterns can indicate a change in the epidemiological pattern of the disease or may be a forewarning of an impending upsurge in the occurrence of the disease. This has been seen in the increasing frequency with which antibiotic-resistant gonococci are being identified,[20] the spread of methicillin-resistant *Staphylococcus aureus*[21] within and between hospitals, and the increasing identification of vancomycin-resistant enterococci as well as of multiresistant *M. tuberculosis* (see Chapters 15, 33, 25, and 39). A variety of molecular tools are now available that provide highly specific identification of a strain or substrain of an organism. Methods for both phenotyping and genotyping are now used. Techniques such as the polymerase chain reaction (PCR), genome sequencing, immunoblot electrophoresis, and a variety of DNA and RNA probes have given high sensitivity and high specificity to the detection of organisms in various tissues and to the precise identification of the particular strain causing a given epidemic. Highly specific antibody identification is also now possible through commercially available monoclonal antibodies. New emerging technologies, such as proteonics and others, are adding to our ability to further identify pathogens (see Chapter 3). These techniques make it possible to follow the spread of an organism in an epidemic and to differentiate between exogenous reinfection and endogenous reactivation.

The serology laboratory also contributes to surveillance by identifying and/or confirming the presence of a specific disease. Usually, two serum specimens are obtained from each individual, one during the acute phase and one during the convalescent phase of illness, to demonstrate a significant change (usually fourfold) in titer. However, if only a single serum specimen is obtained, the occurrence of a specific disease may be suggested if the antibody titer to that disease is

elevated beyond a certain value or by the presence of IgM antibody. Also, if elevated titers are found in serum specimens from a group of patients who had similar illnesses, then these single specimens can be of assistance in making the diagnosis (see Chapter 1).

4.7. Hospital Reporting

The reporting of infectious diseases among hospitalized patients, previously hospitalized patients, or outpatients is a valuable and important source of information. These infections may be truly hospital acquired (nosocomial) or community acquired (see Chapter 26). Community-acquired infections among patients admitted to a hospital reflect the occurrence of infectious diseases in the community. Infections that develop among hospitalized patients or outpatients may represent an endogenous or a exogenous source of infection. If exogenous, the source may be another patient, hospital employee, rarely a visitor, or the hospital environment. An exogenous source may reflect a community problem. Endogenous infections reflect organisms from the patient who may have become colonized from a community source. Computerized administrative data systems can strengthen the hospital surveillance program (see Chapter 26).

4.8. Surveys

Surveys can provide information concerning the prevalence of disease. Clinical surveys may include questions related to the occurrence of a disease, physical examination such as spleen surveys to identify patients with malaria, or diagnostic tests such as skin tests to determine the prevalence of histoplasmosis or tuberculosis. In some countries, blood smear surveys may be used in surveillance for malaria. Other types of surveys include household surveys, such as the National Health Interview Survey, which includes 55,000 households surveyed annually; cluster surveys, such as are used in evaluating immunization programs; and telephone surveys, which can be used to estimate the magnitude of an outbreak of a disease.

Serological tests for certain bacterial, rickettsial, and treponemal infections carried out on a representative sample of a population can provide prevalence data for different age, sex, and geographic segments of the group tested. Incidence data can be obtained by demonstrating the appearance or rise in antibody titer to a given infection in two serum specimens spaced in time such as the start and end of an epidemic, military service, or a college year; the occurrence of recent infection can also be demonstrated in a single specimen by determining the presence of specific IgM antibody for that infectious agent or antibody reflecting early infection. The uses of seroepidemiology are presented in more detail in the companion book on viral infections.[22]

4.9. Animal Reservoir and Vector Distribution

Animal reservoir and vector distribution studies are important in maintaining surveillance of zoonotic and arthropod-borne diseases. Information about rabies in animal reservoirs in a specific geographic area has been and remains important in making a decision concerning the need to treat a human exposed to an unidentified animal. The knowledge that tularemia is occurring in animals or that ticks infected with *Francisella tularensis* are present in an area would support reports of suspect cases of tularemia in humans. Similar studies are in progress to define the distribution of Lyme disease, which is caused by *Borrelia burgdorferi* whose vector is one of several Ixodid ticks. Knowledge about the occurrence of plague in prairie dogs or rodents can be important in evaluating data concerning possible cases of human plague. Surveillance of animal rabies is important as a warning system for the potential occurrence of human rabies. Monitoring the occurrence of avian influenza in birds has been important as concerns the development of influenza in humans due to infections with the avian influenza virus.

4.10. Biologics and Drug Distribution

The utilization of biologics and drugs for treatment or prophylaxis of a disease may be used to monitor disease occurrence. For example, in an outbreak of diarrheal disease, the increasing sales of antidiarrhea medications by pharmacies serve to corroborate the occurrence of disease as occurred in the epidemic of cryptosporidiosis in Milwaukee in 1993.[22A] Similarly, an increase in requests for immune serum globulin can be a clue to the occurrence of cases of hepatitis A.

4.11. Demographic and Environmental Data

Demographic and environmental data are necessary to analyze disease occurrence data effectively. Such data may include age, sex, occupation, residence, or other personal information. Incidence rates cannot be determined until denominator data concerning the population are available. For example, when an increase in the number of isolations of *Salmonella eastbourne* was noted, an analysis of cases by age showed a significant number of cases among young children.[23] This fact was an important clue in leading the investigators to identify chocolate candy as the vehicle of

infection. The ability of new molecular and electrophoretic techniques to identify the specific strain of organisms such as *Salmonella* has allowed epidemics in different geographic areas to be interlinked and a common commercial source identified.[24] The problem of multiple drug resistant tuberculosis in New York City prisons is an example of antibiotic sensitive testing showing the relationship of these cases that occurred in a number of prisons (see Chapter 40).

4.12. News Media

Another useful source of surveillance information is public information gathered through the news media. It is not uncommon for the occurrence of a disease, and especially an epidemic, to be first noted by the news media. Additionally, the news media can perform an important role in alerting the public to the occurrence of a disease epidemic, and thus stimulate the reporting of cases that otherwise might not have been diagnosed or reported. In an epidemic of botulism associated with a restaurant in a western state, radio reports alerted a patron of the restaurant to the possibility of exposure after the patron had returned to his home several hundred miles from the restaurant.[25] At the time he heard the radio report, he was experiencing some symptoms. Accordingly, he sought medical assistance, botulism was diagnosed, he was successfully treated, and another case was reported. The national epidemics of *Escherichia coli* 0,157:H7 in spinach and salmonella in peanut butter are other examples of the media in surveillance.[25A,25B]

5. Routine Surveillance

As previously indicated, routine surveillance of a specific disease will not include all the data sources discussed above. The methods that provide the most accurate information collected in a practical and efficient manner that satisfies the objectives of the surveillance program should be utilized. If more information is needed concerning occurrence of the disease, then additional sources of information can be incorporated into the surveillance system.

The need for completeness of reporting varies according to the incidence of the disease under surveillance. For those diseases that either normally do not occur in an area or occur at a very low incidence, it is essential, for control purposes, that all cases be reported. Examples (in the United States) include plague, yellow fever, poliomyelitis, human rabies, measles, hanta virus disease, avain influenza, and agents of boterrorism.

On the other hand, to maintain surveillance on diseases that commonly occur, it is not critical for all cases to be reported. In the United States, it is estimated that only 1% of cases of salmonellosis, for example, and 15–20% of cases of viral hepatitis are reported. The fact that all cases are not reported should not reduce the effectiveness of surveillance, since it is generally the trends and patterns of disease occurrence that are important in the detection of problems and implementation of control and prevention measures. Changes in the trend should reflect real changes in the occurrence of disease and not changes reflecting a variation in the methods of surveillance. If the methods of obtaining the surveillance data have not changed significantly during a period of time, the case definition has not changed, and the data collected are a representative sampling of the cases that have occurred, then these data should be suitable for determining the trend of the disease. However, a change in the methods used to collect the surveillance data, followed by a change in the reported occurrence of the disease, may be falsely interpreted as a change in the incidence of the disease. An example of this artifact could have occurred in the national *Shigella* surveillance program that was initiated in 1964, with routine reporting from 17 states. Several years later, the remaining states began reporting their isolates; the sudden increase in reported cases could have been misinterpreted if attention had not been given to the mechanics of the surveillance program.[26] Similar artifacts in surveillance data have occurred in the national AIDS surveillance program. As the definition of a case of AIDS has been modified to accommodate new knowledge concerning the clinical manifestations of the disease, the overall surveillance data have reflected these changes.[27]

Case reporting of certain diseases may be discontinued because effective control measures are not available. One such example is streptococcal infections, which may give the uninformed the wrong idea that these infections are no longer of importance.

To validate surveillance data, various methods have been used. These include (1) active surveillance, that is, physicians in the reporting area can be called and asked if they reported all cases of the disease among the patients within a specific time period; (2) hospital records can be checked by means of a prevalence study to see that all notifiable diseases have been reported; and (3) laboratory reports from hospital and public health laboratories for a given disease can be compared to the cases reported to the health department.

6. Reporting

In general, detailed individual case data are not necessarily useful in surveillance programs. It is the analysis of

collective data that provides meaningful information. If more specific case information is necessary, then individual cases can be traced back and additional data obtained.

The quality of a surveillance program is as good as the quality of the data collected. In morbidity reporting, an integral component is the person who has the responsibility for reporting the occurrence of the disease. Most frequently, this is the person who has medical responsibility for the patient, and usually that person is a physician. This responsibility may be delegated to someone else, such as the physician's nurse or, in a hospital, infection control practitioner, the house staff or the administrator. The increasing use of computers by hospitals and large health maintenance organizations (HMOs) for recording diagnoses and the development of linkage systems for such data provide new means of collecting and evaluating surveillance data. In reporting cases of any disease by any means, confidentiality of the patient must be respected and maintained. The Health Insurance Portability and Accountability Act (HIPPA) law concerning patient confidentiality does allow the reporting of patient data but emphasizes the need to maintain confidentiality of the patient (Ref).

In the United States, every state has a law indicating the occurrence of which diseases must be reported and the mechanism of how they should be reported and to whom. Additionally, there usually is a penalty assessed, a monetary fine, prison time, or demerit system that will prohibit renewal of medical license of a reportable case is not reported. However, it is not apparent that any penalty has ever been assessed. The reporting from the States to CDC is a voluntary system and as previously stated the diseases to be so reported are discussed and subject to be modified each year as discussions between the CDC and the state epidemiologist. Within a community, cases are reported to the local health authority, such as a city health department. At regular intervals, usually weekly, these cases will be reported to the state health department. In the United States, the weekly totals and selected individual case data will be reported to the CDC. Many local health departments report to the state health department by computer. All state health departments report their data to the CDC via computers. The development of worldwide systems of communication such as the Internet and World Wide Web has yielded a global method of making such data widely available. The MMWR and the *WHO Weekly Record* are available in these systems. Computer reporting by health-care physicians has been initiated in France[29] and in China.[30]

6.1. Motivation

The diligence with which cases are reported reflects the motivation of the person responsible for reporting. Physicians frequently do not wish to assume this responsibility because of the constraints on their time and the low priority they give to reporting. Also, they may not be aware of state law that mandate reporting of specific diseases. They may not know how to report. There needs to be some motivation developed for reporting other than that related to disease-reporting laws. Motivation may result from being a participant in a public health project or from professional or personal gain. A report summarizing the surveillance data (see Section 9) may be motivational (as well as educational), so that the reporter does recognize that some action results from disease reporting. Motivation may also be derived from knowledge that surveillance data can support the development of effective control and prevention programs, with a decreased incidence in the occurrence of disease.

Reporting may be stimulated by the availability of an epidemiologist to provide assistance to the reporting physician on request. Another source of motivation may be that the reporting of surveillance data results in important clinical and therapeutic data being made available to the practitioner. For example, the increase in antibiotic-resistant strains of *Neisseria* gonococci reported through the CDC's surveillance program is important information for practicing physicians to have when they see a patient, make a clinical diagnosis of gonorrhea, and want to initiate therapy immediately. Another example is the increasing number of reports of antibiotic-resistant *Mycobacterium tuberculosis*, which is a significant problem to clinicians as well as to public health professionals. Also, the worldwide problem of resistant strains of the pneumococcus has been another serious situation as is the problem of the increasing number of reports of community-acquired multiple-resistant *Staphylococcus aureus* (MRSA) (see Chapter 34), the increasing resistance of Neissaria gonorrhea (see Chapter 16). These examples of the application of surveillance data to the practice of medicine can serve to motivate physicians to participate in surveillance activities. Disease reporting can also be stimulated by making specific therapeutic drugs available to the physician on notification of the occurrence of a specific disease. In some communities, reports of hepatitis A result in serum immune globulin being made available for prophylactic use. A report of a case of botulism may lead public health authorities to make botulinum antitoxin available. Reports of certain tropical parasitic diseases make it possible for physicians to obtain certain therapeutic drugs from the CDC not otherwise available. The availability of a drug exclusively from the CDC in the early 1980s to treat cases of *Pneumocystis carinii* pneumonia led to recognition of a new disease, AIDS, in 1981.[31]

A reward system for reporting can be used. The reward can be publicity given to the reporting physicians by listing their names in the surveillance report or in a scientific paper

summarizing the surveillance data. A monetary reward system has also been tried, with an annual payment or a specific amount of money being given for each report submitted. This activity was not very successful, however, and is no longer being practiced.

Health officials must recognize the negative effect of a reporting mechanism that is too complex or that demands excessive expenditure of time on the part of the reporter. If reporting of cases brings adverse publicity to the patient, physician, hospital, or community, surveillance will be inhibited. Adverse publicity that leads to a loss of money or to legal action against the reporter or hospital also has a negative effect on the reporting of disease. Some countries choose not to report quarantinable diseases to the WHO because of the knowledge that publicity concerning the occurrence of those diseases may have an adverse effect on the movement of people and goods across their borders.

6.2. Ease of Reporting

To stimulate reporting, the mechanisms must be simple and yet compatible with an effective and sensitive surveillance system. There must be a relatively easy mechanism by which cases can be reported to the public health authorities. However, the information being requested must provide adequate data for developing a meaningful and practical control and prevention program. It is important to request only data that meet the objectives of the surveillance program. If superfluous data are requested and collected but not used, the reporter will question the surveillance effort and support for the program will decline.

Reporting from the health-care practitioner to the local health department could be simplified to the extent that when the diagnosis of a reportable disease is made and entered into the health-care providers' computer that can be programmed to automatically report the case to the local health department. Only the patients' data that should be reported would be provided to the local health department. Additionally, the local health department's computer can be programmed to report the reportable diseases, either in singularly or in batches, to the next level of reporting (regional, district, and/or state). Thus, all reporting from the health-care provider (or laboratory) to CDC can be accomplished by computers.

6.3. Case Definition

It is important in developing a surveillance program that *specific* case definitions be developed and publicized so that those persons participating can accurately report cases. The definition must be simple, acceptable, and understandable and not incorporate diagnostic criteria that are difficult to comprehend. If laboratory test results are part of the definition, the test must be readily available and inexpensive and not demand a great deal of the patient. It is also important to consider whether only confirmed cases should be reported or whether reporting should also include cases that are less definite as cases of the specific disease and are classified as presumptive or suspect cases of the disease; if so, the definitions of these categories must be acceptable and publicized. The CDC has developed and published a compilation of case definitions for public health surveillance that standardizes definitions for all the diseases reportable in the United States.[8]

6.4. Passive Reporting

Surveillance reporting may be passive or active. Passive surveillance is the routine reporting in which case reports are initiated by the health care provider. Preprinted postcards or reporting forms and stamped envelopes routinely supplied to the reporter can be used to report the requested surveillance data. These cards can be mailed individually or at weekly or monthly intervals, summarizing all cases seen during that time interval; negative reports, i.e., the lack of occurrence of cases, can also be requested. Some states divide the reportable diseases into those commonly seen and those only rarely seen. The reporting official is asked to provide a negative report if no cases of the common diseases are seen and to fill out the form for a rare disease only when a case is actually seen. The reporting form can be a general form suitable for a number of diseases or a specific form used only for a single disease. Special forms can be developed if more detailed data are desired.

Reporting to the local public health office may be done by telephone. The report may be taken by a clerk during working hours or tape-recorded if phoned in outside working hours. The tape recording can be subsequently transcribed by a clerk, who can call the physician if more data are required. To stimulate reporting from throughout an area such as an entire state, a toll-free telephone system can be established. It has been demonstrated that the availability of an automatic telephone-answering service for use at any time has stimulated reporting of disease by physicians. Passive reporting can be improved as health-care providers better utilize personal computers in their practice. This could stimulate better and more rapid reporting and decrease the error rate due to mishandling data.

6.5. Active Reporting

An active surveillance system can be instituted to improve the opportunities to obtain surveillance data; it can

be used for routine surveillance or be an integral part of a special surveillance program established to monitor a specific disease such as during an epidemic. In active surveillance, public health officials needing the information contact the reporter at regular intervals and specifically ask about the occurrence of the disease(s) under surveillance. Thus, there is an active attempt by public health officials to obtain disease occurrence information from the reporter. The introduction of an active surveillance system may greatly increase the number of reported cases of a given disease and may even simulate an epidemic. The users of the surveillance data must be thoroughly informed of such changes in surveillance methods and an interpretation of the increase discussed in an editorial comment. While this system increases the sensitivity of reporting, it also increases the cost of surveillance due to the time needed to make active contact with the reporter.[32]

6.6. Sentinel Physician Reporting

A sampling system that can incorporate either active or passive surveillance is known as a sentinel reporting system. Depending on the size of the community, the degree of reporting desired, and the disease(s) under surveillance, the sentinel physicians may be a sample drawn from all practicing physicians or from among certain specialists who are more likely to see cases of the disease under surveillance. If a patient with the disease under surveillance may be seen by any physician, then the sample should be drawn from among all practicing physicians; however, if a childhood disease is under surveillance, then pediatricians and family practitioners would be the group from which the sample is drawn. The same sentinel physicians can be requested to report regularly, or alternating sentinel physicians can be selected to report weekly or monthly. If the reporting physicians were selected randomly, then the reported cases may be extrapolated to project the total number of cases of the disease that occurred in the area covered by the physicians, weighing each physician's reported cases according to the size of his or her practice. This will allow a fairly accurate estimate of the total cases to be made. However, if the sentinel physicians were not randomly selected or if they were volunteers, the total number of cases can only syndromic reporting be approximated from the number reported.

6.7. Laboratory Surveillance

Disease surveillance can also be maintained by regular monitoring of laboratory reports for the identification of etiologic organisms for diseases under surveillance. This system may be of secondary importance in that it serves to confirm a clinical diagnosis, or it may be of primary importance in identifying the etiology that was suspected by the clinician. For example, a case of pulmonary tuberculosis can be fairly accurately diagnosed on the basis of history and clinical evidence, including radiographs and a positive skin test. Identification of the organism in sputum confirms the diagnosis. Additionally, the antibiotic sensitivity of the organism can be determined that will confirm the proper treatment regime. However, with some diseases such as salmonellosis or syphilis, or shigellosis, accurate diagnosis is dependent on the laboratory identification of the etiologic agent. In diseases in which the laboratory plays a key role in identifying the etiologic agent, it is important to use the appropriate media necessary for this identification. For example, in maintaining surveillance for *Vibrio cholerae* in the United States, it is necessary to use special plating media such as thiosulfate-citrate-bile salt-sucrose (TCBS) agar if the organism is to be identified. Another example is the recognition of the importance of *Yersinia enterocolitica*. When 3 weeks of cold maintenance was required for culturing the organism, very few cases of diarrhea due to this organism were identified. With the introduction of a new culture medium (CIN) that eliminated cold storage, rapid identification became possible and cases are now being identified in routine laboratories. DNA/RNA probes and other microbiological molecular methods of diagnosis are becoming increasingly available and used.

Antibiotic-resistant microorganisms have become an increasing serious problem making it necessary for laboratories to perform antibiotic sensitivity testing as appropriate. These data must be reported to the health-care practitioners in the area in order for them to provide the proper therapy.

6.8. Hospital Surveillance

Surveillance can also be maintained by using hospital records (inpatient or outpatient) and hospital databases to detect either hospital-acquired or community-acquired infections. The records can be abstracted by specially trained enumerators or by record-room personnel (see Section 7.7 for further discussion of hospital surveillance, as well as Chapter 26).

6.9. Absenteeism Surveillance

Other methods of obtaining surveillance information depend on the specific disease. For diseases with high morbidity, an effective surveillance program can be developed by noting absenteeism from schools or industry, depending

on the ages of the involved population. All absenteeism during the period under surveillance may not reflect cases of the disease, so that further information may be needed, such as the rate of absenteeism due to other causes. Sickness benefit or insurance claims can also be utilized to develop surveillance data.

6.10. Syndromic Surveillance

Syndromic surveillance is the reporting of disease by the syndrome's signs and/or symptoms and not its etiologic diagnosis. This form of surveillance is commonly in place in developing countries in which physicians or academically trained health-care providers are not located in health clinics but there are health aides who can report. This form of surveillance can portray disease trends for purposes of control and prevention.

With the concern about bioterrorism, syndromic surveillance is being evaluated as an early warning system following the release of a biological agent.[32A,32B]

7. Special Surveillance

Special surveillance efforts can be established when the rate of occurrence of a disease increases either as part of the expected trend of that disease (periodic or seasonal increase) or as an unusual increase (epidemic). Special surveillance programs can also be developed in relation to the identification of a new disease entity; to provide disease data for research or investigation projects; to define the population among whom prevention measures should be instituted, such as vaccination; and also to evaluate control and prevention measures. Once the immediate need for a special surveillance system has been accomplished, the system should either be stopped or a regular surveillance program for that disease should be developed. In 1981, when the first cases of AIDS were reported, a special surveillance program was initiated. Once the national importance of surveillance data was identified, a regular surveillance program was established. All states now routinely report cases of AIDS to the CDC as part of the weekly surveillance program.

7.1. Influenza

Surveillance information concerning influenza is developed from the regular weekly reporting by 122 American cities of deaths from pneumonia and influenza. Reports of outbreaks of respiratory disease and reports of virus isolation from laboratories doing routine diagnostic work also provide surveillance data. To complement this system, at the beginning of the anticipated influenza season, additional surveillance activities are initiated to improve the knowledge concerning the occurrence of the disease.[33] Reports of absenteeism are solicited from selected industries and schools, since increased absenteeism may be one indication of increased influenza activity. Sentinel family practitioner volunteers from throughout the country report the percentage of patients they see in their practice with the clinical diagnosis of influenza. Virus laboratories are encouraged to process additional specimens from patients with symptoms of a respiratory disease, in order to increase the opportunity of isolating influenza viruses and subsequently to report the results to public health authorities. New rapid laboratory methods now facilitate recognition. These special surveillance activities are helpful in increasing the sensitivity of surveillance for influenza. With the advent of avian influenza in Asia, Africa, the middle east, and southern Europe, involving avians and humans, the intensity of surveillance has increased significantly. Countries are urged to report to the World Health Organization human and avian cases as soon as they are diagnosed and to make isolated influenza virus strains available to WHO for potential use in vaccine production. All such strains are being monitored for antigen drift or shift, which is important not only for vaccine formulation, but also to identify a new strain that may have greater ability for human to human transmission.

7.2. Gastroenteritis

During an epidemic of a gastrointestinal illness, such as salmonellosis, special surveillance efforts of a particularly high-risk group can be introduced to improve the information developed concerning the occurrence of the disease. This may include morbidity reporting, laboratory surveillance, case reporting, or field investigations. With these extra data may it be possible to recommend the most appropriate control and prevention measures. CDC initiated PulseNet in 1996 as an international network of public health laboratories that perform subtyping on bacteria that may be foodborne. Currently, the subtyping method is standardized pulse-field gel electrophoresis, with the results compared electronically with a database maintained by CDC. There are thousands of patterns from throughout the world on file. CDC also developed FoodNet in 1996 with the objectives of determining the burden and trends of foodborne illness in the United States. This surveillance program is able to relate illness to specific foods and to assess interventions. This program is a collaboration with the United States Department of Agriculture, the Food and Drug Administration, and 10 participating state health departments that include more than 650 clinical

laboratories. It receives reports of the isolation of nine enteric pathogens (see Chapter 6).

7.3. Guillain–Barré Syndrome

During the swine flu vaccination program (1976), the reported occurrence of Guillain–Barré syndrome among vaccinated persons resulted in the development of a separate, active, surveillance effort involving special reports from neurologists. Surveillance subsequently has failed to associate other influenza vaccines with this reaction.

7.4. Reye's Syndrome

To develop information concerning the possible association of Reye's syndrome with influenza, special surveillance activities and reporting forms were established for use by pediatricians and neurologists, who were more likely than other physicians to see patients with Reye's syndrome.[35]

7.5. Infant Botulism

When the first reports of infant botulism were published, it was apparent that a previously unrecognized public health problem needed defining. Accordingly, a special attempt at developing surveillance data was initiated by alerting public health officials as well as pathologists, pediatricians, and laboratories to the disease entity.[36] A special reporting form was developed so that pertinent information could be obtained on each case. These special efforts resulted in the reporting of additional cases and the accumulation of important epidemiological data that helped to improve our knowledge of the disease. Cases of this disease are now reported as part of the routine surveillance program in the United States.

7.6. Legionnaires' Disease

When this disease was first identified, there were many unsolicited reports of possible cases. In an effort to standardize these data to define the clinical entity better and to develop more useful epidemiological data, a special surveillance reporting form was developed and a specific definition of a case of Legionnaires' disease was publicized.[37] This resulted in important, new data being uncovered concerning this newly described disease entity. Cases of this disease continue to be reported as part of the routine national surveillance program.

7.7. Hospital Infections

Because of the increasing problem of hospital-acquired infections (nosocomial infections), special surveillance efforts have been developed within hospitals to accumulate data that might be useful for instituting procedures to control and prevent nosocomial infections.[38] The development of infection control committees with many responsibilities, one of which is to supervise a nosocomial infection surveillance program, has been of prime importance to these surveillance programs. Special personnel are usually dedicated to this activity. Surveillance data can be collected by various techniques including individual reports from physicians or floor nurses, ward rounds and record reviews by the infection control nurse, and regular review of the laboratory and pathology records. During ward rounds, the infection control nurse seeks clues to infection by asking physicians and nurses whether any of their patients have infections and noting which patients have elevated temperatures, are receiving antimicrobial agents, or are in isolation. The outpatient department and the employee health service can also be kept under surveillance, since infections noted in these areas may reflect infections among inpatients. All these sources of nosocomial infection surveillance data may not be incorporated into the routine surveillance program at the same time. Also, surveillance may be targeted at specific high-risk patients, areas, particularly, intensive care units, or procedures. As with general surveillance programs, the methods incorporated should reflect the specific needs of the program and available resources. Computer-based surveillance has been developed and may utilize hospital databases such as the admission, transfer, and discharge database to track patient movement, the laboratory database to identify particular infections or antibiotic resistance, and the pharmacy database to identify patients receiving antimicrobics. Community-acquired infections may also be brought under surveillance as an addition to the hospital infection surveillance program. The surveillance and recognition of hospital infections are dealt with in greater detail in Chapter 26.

7.8. Arbovirus Diseases

CDC has developed a special surveillance program for arbovirus diseases, called ArboNet, an Internet-based surveillance system managed by state health departments and CDC. This system has been valuable in tracking the spread of West Nile virus infection and diseases from the northeastern United States in 1999 to all contiguous states by 2005.

7.9. High-Risk Population

A special surveillance program can be developed to identify specific disease among high-risk populations who will derive the greatest benefit from a particular prevention measure. For example, this has been useful for both meningococcal and pneumococcal disease for which specific, effective vaccines have been developed and are now recommended for use among specific highly susceptible populations that were defined from analysis of surveillance data. The administration of influenza and pneumococcal vaccine to particular groups has been mandated by the Centers for Medicare and Medicaid (CMS) and computer-based programs have been introduced to vaccinate target groups and prevent lost opportunities for prevention.

7.10. Emerging Infections

The recognition of AIDS in the United States in 1981 raised the question of whether our surveillance systems were adequate to recognize new diseases caused by agents such as Lassa, Ebola, and Marburg viruses, as well as other older agents that were mutating, such as influenza, or the occurrence of antibiotic resistance to common infectious agents such as the pneumococcus, tubercle bacillus, and enterococci. This led to a National Institutes of Health (NIH) conference in May 1989 that dealt with emerging viral infections, their development, surveillance issues, and means of recognition, which has been subsequently published in a book edited by Morese.[39] In June 1991, the Institute of Medicine (IOM) of the National Academy of Sciences convened a 19-member committee to review the broader field of all emerging infections. This report was published in 1992 and discussed six factors that the committee felt could account for the occurrence of emerging and reemerging infections.[40] Their report also discussed some actions including surveillance that could help control these problems. Another IOM committee was named in 2003 to bring these discussions up to date. They extended the list of factors to 13 and stressed the need for new novel surveillance systems to better define the problems.[40A]

The CDC was quick to recognize the need for additional methods for surveillance and control of these infections.[41] The CDC has developed Centers for Excellence for Public Health Information at five universities, part of whose mandate is to develop novel systems of surveillance and to incorporate electronics into surveillance systems. The role of the United States in emerging infections has been defined by Henderson.[42]

7.11. Serosurveillance

The use of serological testing on a regular basis may provide disease occurrence information not available by other less costly methods. A reproducible serological test and a responsive, approved laboratory are necessary ingredients for this activity. Serology may be useful in adding information to regular surveillance methods and reflects clinical and subclinical infections. Another example of the use of serology is seen in communities in which there is an interest in determining the incidence of human immunodeficiency virus (HIV) infections among pregnant women for which a serosurveillance program is developed in order to provide the necessary data. Serosurveillance has also been used to track the movement of West Nile virus activity across the country.

Other special surveillance techniques can be incorporated to handle specific problems. For example, if there is concern regarding foodborne diseases, then in addition to the routine reporting of cases and epidemics, surveillance of potentially contaminated foods can be instituted by utilizing laboratory culturing of foods routinely supplied by commercial sources. The importation of food items from abroad and their nationwide distribution has resulted in interlinked geographically distant epidemics of the same infection. This requires closely collaborative surveillance activities in state health departments working through the CDC and with the Federal Department of Agriculture (FDA). Surveillance of human carriers of certain pathogenic organisms such as staphylococci or salmonella can be initiated if there is concern about the occurrence of disease transmitted by asymptomatic carriers.

8. Data Analysis

Once the data have been collected, they must be collated and analyzed at regular intervals. The analysis can be simple or complex depending on the needs of the surveillance program, time constraints, how the data are to be used, and the personnel and facilities available. In addition to analyzing data in the routine manner (cases per 100 population), other methods of quantitating disease occurrence data are being utilized for some diseases. These methods provide a more realistic appraisal of the impact of the disease's occurrence upon a population. Some of these methods include calculating years of potential life lost (such as in evaluating injuries), number of cases of a disease per exposure day (such as ventilator-dependant pneumonia per ventilator days), and number of cases of a disease per procedure performed (bacteremias per cardiac catheterization). As surveillance becomes more complex and as more data are

handled, computerization of the data may be desirable and necessary. As previously stated, surveillance data can be entered directly into the computer by the reporting office instead of being handled by one or more intermediate individuals. There are software programs available that can analyze the surveillance data and prepare figures summarizing these analyses. One such software program is Epi Info which is used by the CDC to handle the data reported through the country's disease surveillance program, including preparing the data for publication in the MMWR.

Data analysis will usually suggest the best point for intervention. Occasionally, additional data may need to be gathered by additional surveillance activities or by special investigations.

8.1. Frequency of Review

The frequency, type, and complexity of the analyses are dependent on the use of the summary data. A routine surveillance program may require analyses at monthly or weekly intervals; in epidemic circumstances, it may be necessary to review the surveillance data at more frequent intervals, such as weekly or even daily. The data should be analyzed according to the three key epidemiologic variables, time, place, and person.

8.2. Time

When characterizing the data by time, there are four trends to consider. The first is the *secular* trend, which refers to the occurrence of the disease over a prolonged period of time, such as years. The secular trend of tetanus is one of gradually decreasing incidence (Figure 1). The decreasing secular trend of an infectious disease can be the result of the interaction of various factors such as socioeconomic educational, nutritional, and specific and nonspecific immunity factors within the involved population.

The *periodic* trend,which is the second time trend to consider, refers to the temporary variations from the

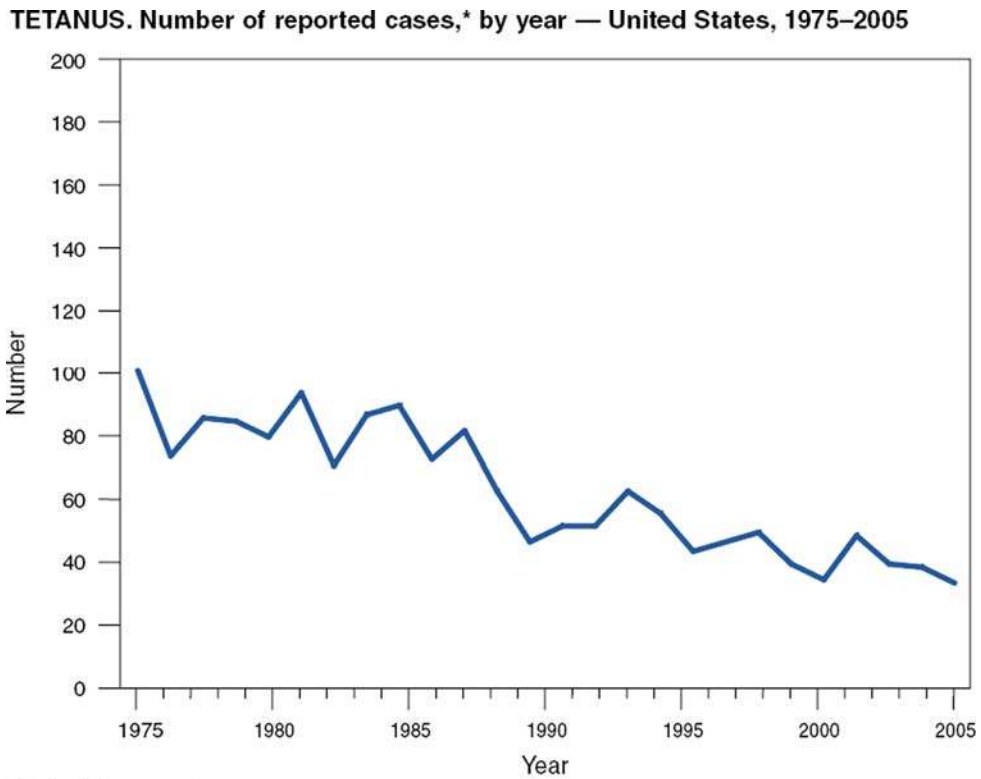

Figure 1. Tetanus: reported cases, United States, 1975–2008.

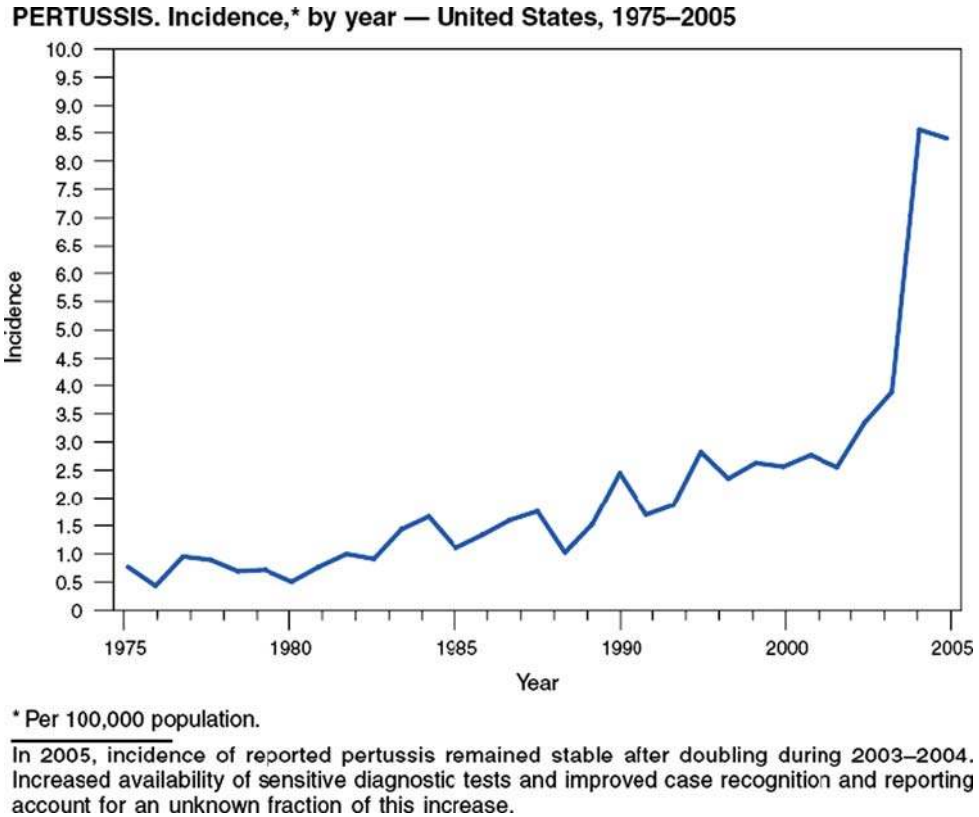

Figure 2. Pertussis: reported incidence rates per 100,000 population, United States, 1975–2008.

secular trend. For example, in considering pertussis, periodic increases in incidence approximately every 5 years can be seen on the background of the overall secular trend of decreasing incidence of the disease (Figure 2). The periodic trends represent variations in the level of immunity (herd immunity) to the etiologic agent influenced by natural infection, variation in the immunity levels of the population reflecting immunization, births, or migrating, or by changes in the antigenic composition of the agent.

The third trend is that of the *annual* variation, which frequently represents seasonal patterns. For example, foodborne diseases are associated with seasonal increases in the late summer and fall that may represent the influence of the ambient temperature on the ability of organisms to multiply in or on their reservoirs and sources, resulting in an increased concentration of organisms for potential contact with susceptible hosts. Additionally, the frequency of picnics and the lack of refrigeration add to the increased opportunity for small doses of agents to multiply to infectious doses.

The fourth time trend is that of the *epidemic* occurrence of the disease. If not noted earlier, an epidemic may be discovered by analyzing surveillance data. This has been seen when cases related to a common source are scattered over several health jurisdictions. For example, a *Salmonella*-contaminated food may result in the occurrence of cases over the distribution route of the food; the individual cases may not serve to alert any one health jurisdiction, but the collection of multiple cases may be distinct enough to be identified as an epidemic. Thus, surveillance can serve as an early warning system for epidemics.

When surveillance data are analyzed for time trends, it is necessary to compare these data with data collected over past years, to accurately interpret the current pattern of the occurrence of disease. Otherwise, changes in the occurrence of the disease may not be definable as being either normal or unusual variations.

8.3. Place

When analyzing surveillance data by place, it is important to recognize that the place represented by surveillance data may represent the area where the patient lives and not the area where the patient became infected. For epidemiological purposes, the important place(s) is where contact

occurred between the patient and the infectious agent or the place where the source of infection became infected. The place of interest will be determined by whether there is interest in control of the current occurrence of the disease or in prevention of future cases. Control measures directed at the site where the host came into contact with the agent can lead to control of additional similar cases immediately related to the initial case, but may not prevent additional cases if there are other sources of the organism that susceptible individuals may have contact with. For example, if a food is contaminated with *Salmonella* in the factory where it is prepared and the exposure of the host occurs in a restaurant serving that food, then closing the restaurant will not prevent cases from occurring in association with another restaurant that also obtained contaminated food from the same factory. Prevention of future cases can be accomplished by eliminating the source of contamination, in this instance, at the food-processing plant.

8.4. Person

Person factors to be defined in analyzing surveillance data may include age, sex, nationality, level of immunity, nutrition, lifestyle (such as sexual practices and intravenous drug use), socioeconomic status, genetic factors, travel history, hobbies, personal habits, and occupation. The evaluation of these factors, frequently referred to as risk factors, is important in further describing the occurrence of disease. For example, age-specific attack rates can be important in determining where control and prevention measures should be directed. Occupation may give a clue as to where intervention measures need to be directed. For example, in evaluating cases of brucellosis, knowing that abattoir personnel who work on the kill floors are at a higher risk of developing disease than personnel in other areas of the plant indicates where control measures need to be directed. In maintaining surveillance of avian influenza, it is important to determine if the patient had contact with avians or could it be the result of person to person transmission.

9. Reports

Appropriate reports should be prepared and distributed to those individuals who participate in the surveillance program as well as those who have a responsibility for preventive action. The purpose of the surveillance report is to communicate with people, to disseminate information, to educate the reader, and to direct, stimulate, and motivate the persons responsible for action. Reports can also be useful in acknowledging contributors to the surveillance activity. The report should not only summarize the surveillance data but also provide an interpretation of the analyses. Control and prevention measures can be discussed. Surveillance reports can also serve to alert the reader to impending problems, newer methods of control and prevention, current investigations, and new information developed from research or field investigations. They can also serve to stimulate better reporting by health-care practitioners.

Reports are usually prepared at regular intervals, such as weekly, monthly, quarterly, or annually. The frequency should reflect the interest in the data as well as the need for distribution of the data as related to control and prevention actions. During an epidemic, the immediate dissemination of data may be critical to stimulating reporting and to the institution of appropriate control measures; thus, daily or weekly reports may be indicated. It may be appropriate to distribute foodborne disease surveillance reports at weekly or monthly intervals during the summer and fall months due to the increased incidence of disease at these periods and then to reduce the frequency of reports during the remainder of the year. Special reports can be distributed as necessary; if rapid dissemination of the information is important, it can be distributed by express mail, telegram, telephone, fax, or computer. Rapid dissemination of information over a wide area may be of such critical importance that use of the public news media should be considered.

In the United States, almost all state health departments prepare and distribute at weekly or monthly intervals comprehensive surveillance reports that summarize their disease surveillance data. The national surveillance data are summarized by the CDC at varying intervals depending on the disease and its frequency. Those diseases reported weekly are summarized in the *MMWR*; other diseases are summarized in specialty surveillance reports that are distributed at regular intervals, from monthly to annually. An annual summary is prepared that summarizes in tables and figures all of the disease occurrence data reported by the states during the previous year and compares these data with data reported during the previous years. Characteristic of many of the CDC surveillance reports and especially of the MMWR is the interpretation of surveillance data and editorial comments that are integral parts of the reports. These reports are available to anyone who would like to receive them. The MMWR is now available by computer through the CDC's World Wide Web server at http://www.cdc.gov/mmwr. A hard copy of all of the CDC surveillance reports can be obtained from the Massachusetts Medical Society or the US Government Printing Office. World surveillance data are collected, summarized, and distributed by the WHO in a weekly and other reports.

10. Evaluation

Once a surveillance program has been developed and has been in operation for several years, it should be reviewed and evaluated. Even though the program is operational, it should not be assumed that it is effectively meeting the objectives of the surveillance activity. Thacker and Berkelman discuss evaluation[2] and the CDC has developed a guide for the evaluation of public health surveillance systems.[7]

11. Limitations of Surveillance

Surveillance of disease is dependent on a series of events that if not followed may prevent the case from being reported. The events include that the disease be severe enough that medical attention is sought and if sought, must be available; laboratory diagnostic facilities may be necessary and should be available; the health-care provider or his or her representative must report the case; and the respective health department must have adequate resources and direction to support the surveillance program. There needs to be consistency in the case definition, in the collection of data, and in the mechanism of reporting. Any alterations in these events may change the apparent pattern of disease. The consistency and stability of the occurrence of these events are vital to the development of reliable surveillance data. In addition to recognition of clinical cases, there may be many infected persons with mild or subclinical illnesses that are not noted in the routine surveillance system. For these cases to be noted, laboratory studies of the distribution of the organism or the antibody to it are required.

CHAPTER 3

Molecular Epidemiology

Lee W. Riley

1. Introduction

Molecular epidemiology is now an established discipline in epidemiology.[1] It is the contemporary stage in the evolution of laboratory-based epidemiology that may have begun with the discovery in the late 1800s of ways to differentiate bacterial organisms by pure culture in artificial media.[2] Molecular epidemiology uses new molecular biology tools to address questions difficult or not possible to address by old laboratory tools. Just as statistical tools have become indispensable in epidemiological investigations and interpretations of epidemiologic data, molecular biology tools today have come to elucidate epidemiologic features of diseases that cannot be easily characterized by conventional techniques. Applied to infectious diseases, molecular biology methods have also come to challenge our traditional notions about the epidemiology of these diseases and have engendered novel opportunities for their prevention and control. This chapter will (1) review definitions commonly used in molecular epidemiology, (2) present an overview of molecular biology methods used to study infectious disease epidemiology, and (3) describe examples of the types of epidemiologic problems that can be addressed by molecular biology techniques, highlighting new concepts that emerged in the process of applying this approach to study bacterial infectious diseases.

2. Definitions

Molecular epidemiology: In Chapter 1, epidemiology is defined as "...the study of the distribution and determinants of health-related states, conditions, or events in specified populations and the application of the results of this study to the control of health problems". Correspondingly, molecular epidemiology can be defined as "the study of the distribution and determinants of health-related states, conditions, or events in specified populations that utilizes molecular biology methods". In molecular epidemiology of infectious diseases, the word "determinants" is emphasized. Furthermore, as we learn more about the biology of agents of infectious diseases, it is becoming evident that disease distribution in a community of hosts may be determined not only by factors such as the distribution of contaminated vehicles, host risk characteristics, and environmental contexts in which these diseases occur, but also by a pathogen's genetic composition.

For example, communicable bacterial pathogens that cause diarrhea are almost always transmitted by the fecal–oral route. Colonization of the intestine is an important prerequisite for these pathogens to facilitate their transmission to new hosts. Similarly, the agent of tuberculosis *Mycobacterium tuberculosis*, which is transmitted by the airborne route, must cause active disease in the host's lungs to assure its transmission to new hosts. An agent of leptospirosis, *Leptospira*, prolongs its survival in a community of hosts by establishing carriage in a mammalian host's kidney tubules so that it can be excreted in urine to infect other hosts. Mechanisms that underlie these organisms' ability to infect a specific target organ, which determines the specific pattern of transmission, are genetically determined. Thus, the definition of molecular epidemiology can be expanded to include the following: a study of the genetic factors that determine and regulate an organism's specific mode of transmission among hosts within an environmental context.

Differentiating molecular epidemiology from taxonomy and phylogeny: In February 2009, a bibliographic search by PubMed using the words "molecular epidemiology" generated 27,822 publications that contained these words in the title or the abstract. Most of these publications dealt with

the laboratory methods used to subtype microorganisms. They did not discuss the use of these techniques to characterize disease occurrence, distribution, or determinants of disease distribution. Thus, the term "molecular epidemiology" is often used to describe studies that should be more appropriately called "molecular taxonomy" or "phylogeny". *Taxonomy* is the science of classification of organisms into naturally related groups based on a factor common to each. *Phylogeny* is the study of lines of descent or evolutionary development of an organism.[1]

Molecular epidemiology, taxonomy, and phylogeny may employ the same molecular biology laboratory techniques, but each is based on distinct principles. In taxonomy or phylogeny applied to infectious agents, the data that are generated are used to describe properties of organisms and their relationships to each other, based on an inferred model. Molecular epidemiology seeks to identify relationships between the etiologic agent of a disease (organism causing the disease), the host, and the environment in which the etiologic agent and the host reside. Both epidemiology and phylogeny as applied to infectious diseases may describe the distribution of particular genetic attributes of a pathogen over time. However, in phylogeny, the relationships of these genetic attributes over time must be guessed, since past evolutionary events cannot be empirically confirmed. That is, phylogenetic analysis seeks to infer past evolutionary events based on a model from a set of observations made with materials available in the present. Epidemiology focuses on events of the present or the recent past. It uses analytical and empirical study designs to identify factors that predict the relationship of attributes of pathogens to disease distribution in place, person, and time. It attempts to identify factors that determine disease transmission, manifestation, and progression. In molecular epidemiology, the hypotheses that are generated are testable or can be made to be testable empirically when enough study subjects are identified. Finally, epidemiology is always motivated by an opportunity or possibility for intervention and prevention. Thus, an application of a molecular biology technique to type an organism per se does not by itself constitute molecular epidemiology. However, it should be stressed that the disciplines of taxonomy and phylogeny play an important role in the discipline of molecular epidemiology, and this idea is reviewed in detail in a separate reference.[1]

Terminologies introduced in this chapter are based on definitions recommended by the European Study Group on Epidemiological Markers[3] and the Molecular Typing Working Group of the Society for Healthcare Epidemiology of America.[4] Others were adapted from a reference book *Molecular Epidemiology of Infectious Diseases: Principles and Practice*.[1] The terminologies below are mostly used in ways to apply to prokaryotic organisms.

Discriminatory power: The ability of a laboratory test to generate distinct and discrete units of information from different isolates, usually at a subspecies level.

Isolate: A population of microbial cells in pure culture derived from a single colony on an isolation plate and identified to the species level.

Strain: An isolate or a group of isolates exhibiting phenotypic and/or genotypic traits belonging to the same lineage, distinct from those of other isolates of the same species.

Clone: An isolate or a group of isolates descending from a common precursor strain by non-sexual reproduction exhibiting phenotypic or genotypic traits characterized by a strain typing method to belong to the same group.

Type, typing information, taxonomic unit, or marker: A specific and discrete unit of information or character belonging to a strain displayed upon application of a strain typing procedure. (e.g., antibiotic resistance pattern, serotype, electrophoretic banding pattern, allele).

Genotype: A genetic characteristic of a cell or an organism according to its entire genome or a specific set of genetic loci (allele).

Phenotype: An observable characteristic expressed by a cell or an organism, such as drug resistance, virulence, and morphology.

Biotype: A taxonomic unit of a microorganism belonging to one species based on a panel of biochemical tests.

Serotype: A taxonomic unit of a microorganism based on antigenic properties of a distinct set of surface structures.

Pathotype: A taxonomic unit of a microorganism that describes a pathogenic variant of a species or subspecies of microorganisms that normally colonize a host. Also called *pathovar*.

Allele: A nucleotide sequence variant of a gene at a particular locus.

Single nucleotide polymorphism (SNP): Small changes or variation in corresponding nucleotide sequences at a given locus (e.g., corresponding locus TTAGGTCCTTTA in strain 1 and TTTGGTCCTTTA in strain 2 differs by a single nucleotide in the third position).

Microsatellites: DNA sequences containing tandem repeats of a short sequence (e.g., CCG repeated 10 times in succession). Most often used in reference to such sequences in eukaryotic cells.

3. Methodology

It should be emphasized at the outset that molecular biology methods are no more special than any other methods—laboratory or non-laboratory—used in epidemiology. Curiously, however, when biochemical laboratory

methods are used to characterize organisms in an epidemiologic investigation, we do not use the term "biochemical epidemiology". For some reason, when molecular biology methods are used in an epidemiologic study, the study is described as "molecular epidemiology". This probably results from a peculiar human habit of glorifying certain characteristics over others. For instance, it is more fashionable in research universities to call a department doing the same type of research a "molecular biology" instead of a "microbiology" department. Molecular epidemiology is epidemiology. In truth, molecular biology methods are nothing more than one of many tools used in epidemiology to order data into separate units or strata so that they become amenable for different types of analytical procedures.

All laboratory-based methods used to type microorganisms (*typing systems*) fall into *phenotypic* and *genotypic* methods, as described by Maslow et al.,[5] Tenover et al.,[4] and Lipuma.[6] Most of the "conventional" laboratory typing methods fall into phenotypic methods, which are based on the detection of phenotypes or characteristics expressed by an organism. Strain typing methods based on genotypes rely on the analysis of nucleic acid contents and gene sequence polymorphisms (chromosomal DNA, extrachromosomal DNA, and RNA). Nowadays, with routine applications of molecular biology tests, the distinction between "conventional" and molecular biology laboratory techniques may no longer be meaningful. Many standard strain typing procedures today are built upon layers of tests that include both molecular and non-molecular biology techniques.

3.1. Phenotyping Methods

The first step in data stratification as applied to bacterial infectious disease agents is differentiating pathogens from normal commensal or saprophytic bacterial organisms. Commensal organisms reside, metabolize, and replicate in a healthy, immunocompetent host without causing disease. They colonize the skin, mouth, nasopharynx, gastrointestinal tract, vaginal mucosa, and others. A saprophyte is a type of microorganism that grows normally on dead matter, and hence is found in the environment. This initial step separates organisms into species. Microorganism characteristics used to define species include growth, morphologic, biochemical, serologic, functional, and physiologic properties.

3.1.1. Differentiation by Growth and Morphologic Characteristics. Differences in nutritional requirements of bacterial organisms determine their growth characteristics. They can be classified according to whether they grow at all or the way they grow on solid agar culture plates or in liquid media. Morphologically, they may be differentiated by their colony shape, color, texture, smell, or whether they "swarm" on the plate. They are also differentiated by the way they stain (e.g., Gram stain, acid fast stain) as observed under a light microscope, or their shape and size as observed under an electron microscope.

3.1.2. Typing Based on Biochemical Characteristics. Biochemical tests used to differentiate bacteria are based on the organism's metabolic activities. Strains differentiated by a panel of biochemical tests group into *biotypes*, and the tests are thus referred to as biotyping tests. The discriminatory power of a biotyping test depends on the number of biochemical tests used to subtype strains—the larger the number of biochemical characteristics analyzed in a pathogen, the greater the discriminatory power of the test. The tests depend on an organism's metabolic activities, which are sometimes subject to minor changes in growth condition (e.g., nutrient concentration, pH, and temperature) used, and hence the information that is generated may not always be reliable for epidemiologic studies. In developed countries, these tests have come to rely on kits and automated systems, facilitating rapid turnover. However, the large number of tests often needed to subtype a strain renders biochemical classification of pathogens expensive.

3.1.3. Typing by Serologic Characteristics. Another frequently used phenotyping method is based on a characteristic antigen-specific serologic (antibody) response induced by an invading organism in a mammalian host. Bacterial antigens that induce antibody response used for serologic classification include proteins and polysaccharides. For example, the species *Escherichia coli* characterized biochemically can be further subtyped into a "serogroup", based on the organism's characteristic somatic antigen (O-polysaccharide). A numerical designation is assigned to an *E. coli* strain carrying a characteristic O-polysaccharide that induces an antibody response (e.g., O157). The same strain, if further subtyped based on its flagellar protein (H-antigen), is classified as a "serotype". It will then be given an O:H designation (e.g., O157:H7). The genus *Salmonella* is biochemically separated into species and subspecies. They are further subtyped serologically according to their O and H antigens. Unlike *E. coli* serotypes, *Salmonella enterica* subsp. *enterica* (subspecies I) serotypes are given a descriptive name rather than a numerical designation, e.g., *S. enterica* serotype (or serovar) Typhimurium or *S. enterica* serotype Enteritidis. Nearly 1,500 serotypes of *S. enterica* subspecies I are currently recognized.[7] The specific serogrouping or serotyping assays include bacterial agglutination test with a panel of antigen-specific antisera, enzyme-linked immunosorbant assay (ELISA), latex particle agglutination, Western blot (or immunoblot) analysis, or a modification of these tests.

One limitation of serotyping is that different strains from the same species or even strains from different species

could carry cross-reacting antigens, which can result in false-positive tests. On the other hand, strains that do not express typing antigens are classified as non-typeable (e.g., non-typeable *Haemophilus influenzae*). Serologic tests, on the most part, are simple to perform, but they require maintaining a stock of typing polyclonal or monoclonal antisera. For example, a large number (~200) of antisera need to be used to serotype *Salmonella*. Thus, serotyping could be expensive and time consuming, and is usually confined to reference laboratories.

3.1.4. Typing by Functional or Physiologic Characteristics. Other ways to differentiate bacterial isolates involve examination of their response to specific manipulations. They include identifying differences in susceptibility to antimicrobial agents (antibiograms), lysis by or susceptibility to bacteriophages (phage typing), patterns of association with tissue culture cells (cell culture assays), toxigenicity, survival under in vitro or in vivo stress, and metabolic enzyme expressions (multilocus enzyme electrophoresis, or MLEE). These are reviewed in detail elsewhere.[1]

3.2. Genotyping Methods

Genotying or nucleic acid-based typing methods are ultimately based on the nucleic acid sequence differences in the chromosomal or extrachromosomal nucleic acid contents. As opposed to hundreds of ways to phenotype bacteria, all genotyping tests can be grouped into a variant of just three basic analytical procedures—(a) hybridization, (b) gel electrophoresis, and (c) nucleic acid sequencing. This allows for the use of common equipment and standard reagents to analyze many different types of infectious agents. Furthermore, genotypic characterizations of pathogens facilitate standard information storage and data analyses, interpretation, and communication, which are all amenable to computer-assisted manipulations.

In bacteria, genotyping analyses are based on comparison of two types of DNA: the genome and the extrachromosomal DNA. Typing systems based on the analysis of the genome fall into those designed to compare differences based on nucleotide changes that occur in parts of the genome (microdiversity) or the entire genome (macrodiversity). These typing methods, of course, had to be developed in place of direct whole genome DNA sequence analysis, which, despite recent advances in the sequencing technology, remains cumbersome and expensive for bacterial organisms (although no longer the case with viruses). Further detailed reviews on this topic are mentioned at the end of this chapter (Suggested Reading).

3.2.1. Extrachromosomal DNA Genotyping Methods. For bacteria plasmids are the extrachromosomal DNA elements used to type strains. Plasmids are covalently closed circular DNA that carry genes that may encode characteristics such as antibiotic resistance, virulence factors, or other functions that provide selective advantage to the organism but are not essential for its growth or survival. In fungi or protozoas, extrachromosomal elements used for typing may include mitochondria[8] and kinetoplasts (schizodeme analysis).[9]

Plasmid-based typing is an example of an electrophoresis-based strain typing procedure. It compares differences in molecular weight (MW) and the number of different plasmids a bacterium may carry. Nucleic acids and proteins are negatively charged. Plasmids, thus, can be resolved electrophoretically in an agarose gel matrix according to MW. That is, the separation of these molecules depends on their drag through the gel matrix as they migrate toward the positive charge pole. Large MW plasmids migrate more slowly in the gel matrix than low MW plasmids. Thus, depending on the number of different MW plasmids, each strain represented by a single electrophoretic lane will generate a banding pattern, a "fingerprint", or a profile, that can then be compared across multiple lanes (Figure 1).

In one early study designed to validate the discriminatory power of plasmid profile analysis of bacterial pathogens, Holmberg et al. compared *S*. Typhimurium isolates from 20 well-documented outbreaks by phage types, antimicrobial resistance patterns, and plasmid profiles.[10] They found that among nine outbreaks in which non-outbreak isolates were also examined, the plasmid profile analysis was able

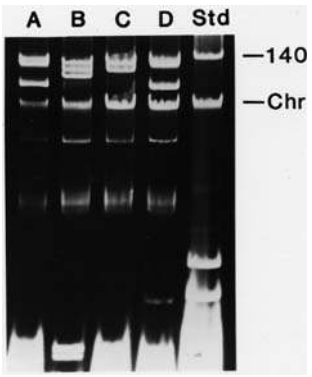

Figure 1. Agarose gel electrophoresis of plasmids (plasmid profile) extracted from drug-resistant *Salmonella enterica* serotype Typhimurium isolates from children with diarrhea in Brazil.[75] Lanes A–D show distinct banding patterns. All isolates carried a 140 MDa plasmid as well as lower MW plasmids. "Chr" denotes chromosomal DNA. MW marker standard is shown in lane marked "Std".

to distinguish outbreak-related isolates from non-outbreak-related isolates more frequently than the other methods (phage typing and antibiogram), suggesting that the plasmid profile analysis was more discriminatory than the other methods used to type strains at that time.

One drawback of the technique is that the procedure depends on the presence of at least one plasmid in a bacterium. If isolates carry only one or two plasmids, the patterns generated will not be sufficiently discriminating enough to distinguish the strains as related or unrelated. Isolates that contain only one or two plasmids of identical MW need to have the plasmids digested with endonucleases (enzymes that cut DNA molecules at a specific sequence site; see details under "Restriction Endonuclease Analysis or REA") to generate smaller fragments that can then be electrophoretically resolved. Another potential problem with this method is that plasmids on prolonged storage of a bacterium can be spontaneously lost, which can affect reproducibility of the typing method. Although plasmid profiles are relatively easy to perform and interpret, it does require a laboratory equipped for basic molecular biology techniques, including DNA extraction, restriction endonuclease digestion, electrophoresis, and photodocumentation of the results.

3.2.2. Genome-Based Typing Methods. In genome-based typing methods the entire genomic content of a microorganism is compared among different strains (macrodiversity analysis). There are three basic genome-based typing methods used in epidemiologic investigations, which are based on (1) allelic differences that occur within restriction endonuclease recognition sites in a genome, (2) comparison of multiple nucleotide sequences of whole genomes (called comparative genomics), and (3) whole genome hybridization patterns (see below for the description of hybridization) obtained from arrays of thousands of distinct short DNA fragments representing the whole genome fixed onto a glass slide or nitrocellulose filter ("gene chip" or microarray). The latter two methods have only recently begun to be applied to epidemiology.

3.2.3. Restriction Endonuclease Analysis (REA). Bacterial organisms express enzymes called restriction endonucleases that recognize unique sequences of several nucleotides in length and cut the DNA molecule at a specific position. They are called restriction enzymes because bacteria use these enzymes to eliminate (restrict) foreign DNA accidentally introduced into them. Thus one enzyme may generate distinct sets of DNA fragments from two different strains if the strains have a sequence difference at the corresponding restriction sites. Comparison of electrophoretic patterns based on the number and differences in MW of cut DNA fragments is called restriction endonuclease analysis (REA) or restriction fragment length polymorphism (RFLP) analysis.[11–13]

Enzymes that cut DNA molecules at recognition sites that occur frequently throughout a microorganism's chromosome are colloquially referred to as "frequent cutters". Electrophoresis of DNA fragments generated from such enzymes will produce thousands of overlapping bands upon gel electrophoresis, and the resulting patterns become difficult to interpret (Figure 2A). Two different ways have been developed to overcome this limitation, as outlined below.

3.2.4. Southern Blot Hybridization. Southern blot hybridization analysis, named after its developer,[13] is a type of analysis that facilitates detection of a particular DNA fragment of interest among hundreds of other DNA fragments generated by REA. DNA fragments separated in an agarose gel are first transferred onto a piece of nitrocellulose or nylon membrane. The membrane is then exposed to a piece of

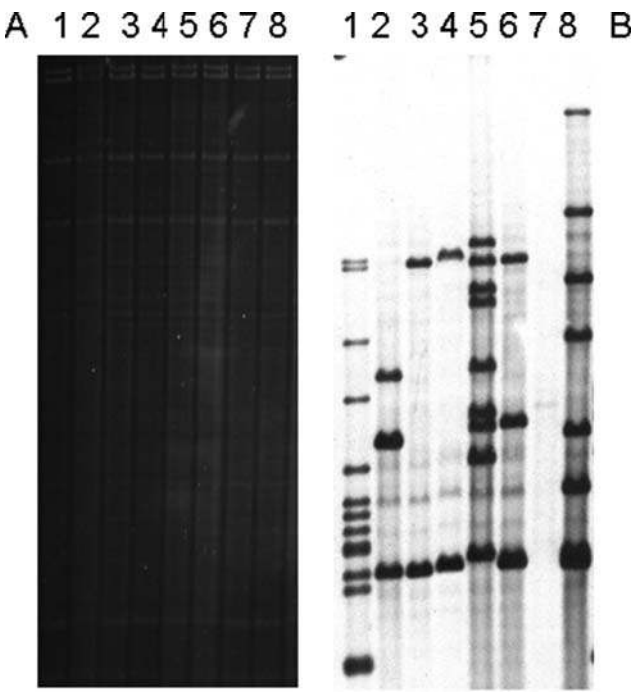

Figure 2. Restriction fragment length polymorphism (RFLP) analysis with Southern blot hybridization of eight clinical isolates of *M. tuberculosis*. Panel (**A**) shows *M. tuberculosis* DNA digested with a restriction endonuclease PvuII. Note the smear pattern in each lane, representing thousands of DNA fragments resolved by electrophoresis in an agarose gel. However, when the DNA fragments of the gel are transferred onto a piece of nylon membrane and hybridized with a probe directed at *M. tuberculosis*'s *IS6110* insertion element, only the DNA fragments that contain this element becomes visualized (**B**). Thus, the patterns generated in the membrane in panel B become interpretable and can be compared among strains.

single-stranded DNA (probe) labeled with a molecule that facilitates visual detection of a selected target DNA fragment. The probe will specifically bind (hybridize) to its complementary DNA sequence embedded in the membrane. For example, a nucleic acid sequence or probe *ATCGGCGATG* will hybridize to a target containing the sequence *TAGCCGCTAC*. Thus, this probe-based detection of target DNA fragments is called hybridization. If the organism of interest harbors more than one copy of the target DNA sequence in different locations in the chromosome, the membrane will show multiple bands (banding pattern) in a single lane, which can be visually detected. Of course, the number of such visualizable bands will be few and will not be obscured by the other fragments in the membrane, which cannot be visualized because they do not hybridize to the probe. This allows for comparison and interpretation of the band patterns (Figure 2B).

This method has been applied to subtype a wide variety of bacterial organisms, and is the current standard method used to type *M. tuberculosis*, in which the organism's repetitive DNA element or insertion element called IS*6110* is used as the target for a hybridization probe (called *IS6110* RFLP).[14] One limitation of this approach is that the DNA sequence selected as a target for a hybridization probe must be present in the chromosome in high copy numbers (usually >5) for the technique to be sufficiently discriminating. Clinical isolates of *M. tuberculosis* completely lacking or having small copy numbers of IS*6110* have been found.[14] In such situations, secondary typing methods must be applied. Another drawback of the RFLP analysis followed by hybridization is that it requires a specialized reference or research laboratory to perform.

When the hybridization typing method uses ribosomal genes (*rrn*) as a target, it is called ribotyping. Ribosomal RNA sequences are highly conserved, especially within members of the same genus. This property can be used, then, to type a wide range of organisms related at the species level, but by the same token, the discriminatory power of ribotyping is low. One study found that *E. coli* isolates obtained from widely separate geographic areas shared identical ribotypes.[15] Thus, for *E. coli*, ribotyping would not be discriminating enough for local epidemiologic studies or regional surveillance, although it may be useful for studying evolutionary relationships.

3.2.5. Pulsed Field Gel Electrophoresis (PFGE). The second way developed to overcome the problem of uninterpretable electrophoretic patterns generated by RFLP is to use endonucleases that recognize rare restriction site sequences ("rare cutters"). Such enzymes will produce very large DNA fragments, which, when resolved electrophoretically, will generate interpretable patterns. However, electrophoresis in agarose gels of large pieces of DNA introduces two additional technical constraints. Linear pieces of DNA $\geq$25,000 bases (25 kilobases or kb) are difficult to resolve by the conventional agarose gel electrophoresis method. They get stuck during migration across the gel matrix. Thus, PFGE was developed in which the orientation of the electrical field across the gel is changed (pulsed) periodically.[16] This allows the DNA fragments to move in different directions, releasing them from the stuck position. The DNA fragment will thus take a path of least resistance along its gel migration toward the positive charge pole.

The second technical obstacle that had to be overcome was the tendency for large DNA fragments to undergo spontaneous autodigestion. This problem was eventually solved by enzymatically lysing and digesting the cell wall and proteins of the test bacterial organism embedded in an agarose gel plug. This releases the bacterial DNA directly into the plug. The released DNA can then be digested within the plug with a restriction enzyme. This prevents autodigestion.

The major advantage of PFGE is that virtually all genome-containing organisms are typeable by this method. In general, genetic changes detected by PFGE reflect genetic events in an organism that occurred in the recent past. Hence, it is a highly informative technique with wide epidemiologic appeal. PFGE is the method of choice used by a national foodborne disease surveillance system called PulseNet, which is collaboration among Centers for Disease Control and Prevention (CDC), Association of Public Health Laboratories (APHL), and the food regulatory agencies, including the United States Department of Agriculture (USDA) and the Food and Drug Administration (FDA). Foodborne pathogens included in the PulseNet surveillance currently include *Salmonella* Typhimurium, *E. coli* O157:H7, *Listeria monocytogenes*, *Campylobacter jejuni*, and *Shigella sonnei*[17] (www.cdc.gov/pulsenet). PulseNet has contributed to detecting, investigating, and controlling multistate outbreaks of *E. coli* O157:H7,[18] *Salmonella* Agona infections,[19] and listeriosis.[20] The network will expand to PulseNet Canada, PulseNet Europe, PulseNet Asia Pacific, and PulseNet South America.

One major limitation of PFGE is that it is technically demanding, requiring an expensive electrophoresis apparatus. Thus, this typing system is currently used only by reference or research laboratories.

3.2.6. Whole-Genome Sequence Comparison. The reduced cost and ability to rapidly sequence large pieces of DNA engendered a new discipline called comparative genomics.[21, 22] With viruses, whose genomes are considerably smaller than those of bacteria, comparative genomics is already applied to directly genotype clinical isolates. That is, hundreds of genomes of viral strains belonging to one species

can now be compared rapidly to each other and applied to address epidemiologic questions. For example, it was the comparative genomics analyses that enabled investigators to conclude that the agent of severe acute respiratory syndrome (SARS) belonged to a group of coronaviruses.[23]

With bacteria, because of the large genome, such comparisons are still not possible for a large number of strains. That is, hundreds of genomes of a single bacterial species cannot be compared because they have not been sequenced. However, new information obtained from comparison of a limited number of whole genome sequence databases is used to develop alternative genotyping methods. For example, at least eight different clinical isolates of *Staphylococcus aureus* have now undergone whole genome sequence analysis. Multiple alignment comparisons reveal several regions of difference. One such region called RD13 containing a cluster of Staphylococcus exotoxin (*set*) genes has been recently exploited to develop a new genotyping method called exotoxin sequence typing.[24]

Whole genome sequence comparison of *M. tuberculosis* H37Rv, CDC1551, strain 210, and *Mycobacterium bovis* AF2122/97 led to the identification of 212 *single nucleotide polymorphism* (SNP) markers.[25] More recently, an analysis of these SNP markers in a global collection of 294 *M. tuberculosis* strains identified six phylogenetically distinct SNP cluster groups (SCGs). SCGs were strongly associated with geographic origin of these isolates.[26]

3.2.7. Microarray Comparisons. Another way to compare whole genomes is based on hybridization patterns generated from thousands of short pieces of DNA (probes) of known sequence representing the genome, arranged on a glass slide or nitrocellulose membrane, often referred to as microarray or "gene chip". Microarrays are a type of DNA hybridization matrix typing method described previously. The hybridization technology is not new, and the microarray technology is just a recent variant of the technology made possible by miniaturization techniques developed in the semiconductor industry.[27–29]

Most microarray-based applications to infectious disease currently focus on taxonomic differentiation or diagnosis, and not on epidemiologic investigations. In one study, a whole genome DNA microarray analysis of 13 vaccine strains of *M. bovis*-BCG found 16 regions deleted in BCG strains relative to the sequenced *M. tuberculosis* H37Rv genome.[30] Kato-Maeda et al. found 25 deleted regions among 19 clinical *M. tuberculosis* isolates by a whole genome microarray approach.[31] Here, they reported that there was an inverse relationship between the proportion of deleted regions in these strains and the percentage of patients with cavitary disease infected with these strains. The discovery that *M. tuberculosis* contained such regions of deletion led some investigators to propose a genotyping scheme called "deligotyping".[32] In this method, clinical isolates of *M. tuberculosis* are compared according to differences in the regions of deletions.

Microarrays facilitate comparison of a large number of strains more rapidly than the whole genome sequence comparisons, but they are dependent on the number and types of DNA fragments that are included in the array, and hence will not be as discriminatory as the latter. Furthermore, they require specialized laboratories equipped with a scanner to read the microarray and expensive software to interpret the hybridization patterns on the chip. Thus, this technology is not likely to become readily available in the near future in most places to conduct epidemiologic investigations.

3.2.8. PCR-Based Genotyping Methods. All of the genotyping methods described above are based on DNA extracted from bacteria that are cultivated in vitro. Culturing bacteria serves two important purposes—(1) makes available large amounts of DNA for the genotype analysis and (2) assures that the genetic material being analyzed represents a distinct bacterial strain, obtained from pure culture.

For bacterial organisms that grow very slowly (*M. tuberculosis*) or cannot be cultivated artificially (*Treponema pallidum*), the above genotyping methods would be difficult to apply. Improper storage of bacterial isolates may also cause them to die, in which case genotyping by any of the above methods will not be possible. Polymerase chain reaction (PCR)-based tests can overcome these limitations. The PCR technology is a powerful and simple molecular biology tool, which is now applied in a variety of ways to genotype microorganisms in taxonomic as well as epidemiologic studies. It should be noted that PCR is only one of several methods called nucleic acid amplification tests (NAAT) used to make multiple copies of a target DNA or RNA of an organism or cells in vitro without culturing the organism or cells. PCR is perhaps the most frequently used NAAT and the most common method applied to subtype microorganisms. There are many excellent books that detail the procedure and are listed at the end of this chapter (Suggested Reading).

3.2.9. Overview of PCR. There are a number of frequently used terms that the reader should become familiar with in the discussion of PCR tests. Those familiar with the procedure may skip this section.

PCR involves multiple cycles of a three-step process: (1) denaturation of double-stranded DNA into single strands, (2) annealing of oligonucleotide primers to target DNA sequences called a template, and (3) primer extension along the template sequence from the primer binding site. These steps are carried out in a plastic microcentrifuge tube containing a reaction mixture of buffers, nucleotides, primers, heat-stable polymerase, and a sample DNA template. DNA

when heated to a sufficiently high temperature will separate into single strands. Separation into single strands of a double-stranded DNA is called denaturation. Thus, in the first step, the sample DNA (template) is usually heated to 95–100°C. Primers are synthetic single strands of DNA (oligonucleotides) of variable lengths designed to bind (anneal) to specific complementary target sites in a DNA template. They can be custom-made commercially. Primers bind to the target sequences when the temperature of the reaction mixture is decreased from a denaturation temperature to an annealing temperature range (~40–60°C). At about 70–75°C (primer extension temperature), a thermostable enzyme called DNA polymerase will add nucleotides (extension) complementary to the unpaired DNA strand onto the annealed primer. In this way, a DNA segment located between the two annealed primers will be copied. This three-step cycle involves change in temperature only—denaturation, annealing, and extension temperature—which is facilitated automatically by a programmable heating device called thermocycler. Depending on the time applied to each of the steps in the cycle, the type of thermocycler used, and quality of the polymerase, a single copy of DNA can be multiplied to more than a billion copies after 30 cycles in less than 3 h. The amplified product can then be visualized in an electrophoretic gel under UV illumination after staining with ethidium bromide.

For PCR tests, the cultivation of organisms is usually needed not so much to make enough nucleic acid material available for analyses, but to assure that the product being analyzed represents a single or pure strain of an organism. For bacteria, if a clinical specimen is obtained from a normally sterile body site such as blood, cerebrospinal fluid, or deep tissue, and it is obtained in a sterile fashion, PCR assay may be performed directly on the specimen itself. The primer sequences could be designed to bind to sequences that are specific to a target organism (e.g., IS*6110* of *M. tuberculosis*). In this way, DNA targets in an organism infecting nonsterile sites (sputum, urine, stool) could be amplified. Blood, urine, and other tissues may contain products inhibitory to PCR, but if the specimen contains a sufficiently large number of the infectious agent of interest, the desired target DNA could be amplified and detected. If a stored organism becomes contaminated with other organisms, or lose their viability, a PCR test can still amplify DNA from that organism, as long as the DNA material is intact. If the primers are highly species specific, a PCR test can distinguish the target sequences from DNA derived from contaminating organisms, thus precluding culturing the target organism from a specimen.

3.2.10. PCR-Based Strain Typing Methods. PCR-based genotyping methods that compare electrophoretic bands are classified into two general categories: (1) those based on MW polymorphism of a single amplified product and (2) those that display band patterns (fingerprints) from multiple amplified products. The former method is often used to type organisms to predict species,[33–35] serogroups, serotypes,[34, 36, 37] or *pathotypes*.[37] The major advantage is that this PCR-based method is considerably simpler than the conventional methods used to group them into species, serotypes, or pathotypes, but its discriminatory power is limited to differentiating organisms belonging to a large taxonomic unit. It does not discriminate beyond these taxonomic units.

More discriminating PCR-based typing methods require generation of fingerprints. These latter techniques can be divided into three major groups (Table 1): (1) those that rely on sequence polymorphism in the whole genome,

Table 1. PCR-Based Strain Typing Methods Used in Epidemiologic Studies

General category of methods	Specific techniques
Methods that rely on sequence polymorphism in the whole genome	Arbitrarily primed PCR (AP-PCR) or randomly amplified polymorphic DNA (RAPD) PCR
Methods based on heterogeneity within endonuclease restriction sites	PCR-restriction enzyme analysis (REA) or PCR-restriction fragment length polymorphism (RFLP) analysis
	Amplified fragment length polymorphism (AFLP) analysis
	Restriction-site-specific PCR (RSS-PCR) analysis
	Amplified ribosomal DNA restriction analysis (ARDRA)
Methods based on interspersed DNA repetitive elements	Extragenic palindromic (REP) assay
	Enterobacterial repetitive intergenic consensus (ERIC) sequence assay
	Mosaic repetitive element PCR (BOX-PCR)
	Insertion element PCR assays (IS6110, IS1245, IS900)
	Short interspersed DNA repetitive element assay (PGRS, VNTR, MPTR, ETR)
	Direct repeat (DR) PCR or spoligotyping
Methods that compare allelic differences in selected target genes by sequencing PCR products	Multilocus sequence typing (MLST), single nucleotide polymorphism (SNP) analysis

(2) those based on heterogeneity within known restriction endonuclease recognition sites, and (3) those that take advantage of repetitive elements interspersed in the target genome.

One relatively new category of PCR-based typing methods is based on comparison of sequences of PCR products of selected gene targets instead of comparison of band patterns by electrophoresis. One example of such a method is called multilocus sequence typing (MLST), discussed below. All of the above methods are described in detail in reference (1). Methods that are most frequently used in epidemiologic investigations are described below.

3.2.11. PCR Typing Methods Based on Sequence Polymorphism in the Whole Genome. Arbitrarily primed PCR (AP-PCR), also called randomly amplified polymorphic DNA (RAPD), are PCR techniques that rely on arbitrarily or randomly designed sequences of primers that anneal specifically to DNA templates in a target organism.[38–40] If a set of these randomly designed primers anneal to target DNA sequences, the intervening segments that are proximal enough to these annealing sites can be amplified and generate products of different MW. Such products will display a band pattern in an electrophoresis gel for each strain. The advantage of this method is that the target nucleotide sequence does not have to be known. The primer sequences are determined empirically until a set that works is found. The final choice of the primer design is based on the generation of reproducible and interpretable band patterns. The major drawback of this test, however, is its reproducibility. Because this technique is based on random sequences of the primers, there is always a risk that contaminating DNA may get amplified. To minimize these nonspecific amplification, the following precautions are taken: (1) DNA templates should be from organisms recovered in pure culture, (2) include a sample in which no template is added (negative control), (3) standardize template DNA concentration in all samples to be tested, and (4) if possible, test all the desired samples in one batch.

3.2.12. PCR-Restriction Enzyme Analysis. The same principles behind REA, RFLP, and PFGE analyses of genomes of pathogens can be applied to PCR products. A PCR product, if it is sufficiently large, 1,000–2,000 base pairs or bp, can be digested with an endonuclease, and the generated DNA fragments can be resolved by gel electrophoresis and visualized. If such amplified products contain nucleotide changes at the restriction sites, varied electrophoretic band patterns will result from the digested PCR products. One drawback of this PCR-REA (or PCR-RFLP analysis) method is that part of the target sequence to be amplified has to be known ahead of time.

3.2.13. PCR Typing Methods Based on DNA Repetitive Elements. Repetitive DNA sequence elements are found in both prokaryotic and eukaryotic chromosomes. A variety of repetitive DNA elements have been identified in bacterial pathogens, which have been exploited to develop PCR-based strain typing assays. All of these procedures use the same approach, in which primers are designed to anneal to target repetitive sequences in the outward direction (outward primers) near the ends of these repetitive elements. The newly synthesized DNA strand extends away into the nonrepetitive sequences. Thus, sequences located between the elements are amplified. Because these elements are interspersed in the chromosome at different locations between species or strains, the amplified products will be of variable number and MW. The size of the amplified products will depend on the distance between the repetitive elements and the quality of the polymerase, and other PCR conditions used. Of course, longer the distance between the repetitive elements, harder it is to amplify such a region.

Table 1 lists some of the major bacterial repetitive DNA elements that have been used for strain typing. One frequently used repetitive element genotyping method is called enterobacterial repetitive intergenic consensus (ERIC) sequence PCR.[41, 42] ERIC sequences are dispersed throughout the bacterial chromosome, especially of Gram-negative bacteria, and are located in extragenic regions.[41, 43] The exact function of ERIC sequences is not known.

Another repetitive element used for typing by PCR is called BOX, first reported in Gram-positive bacterial organisms.[44] BOX elements include mosaic combinations of three subunits, boxA (59 bp), boxB (45 bp), and boxC (50 bp),[44] which are all found in *Streptococcus pneumoniae*. Gram-negative organisms such as *E. coli* and *S. typhimurium* contain *boxA*-like sequences, but not *boxB* or *boxC* sequences. BOX elements have been widely applied to characterize the epidemiology of pneumococcal diseases.[45–48]

3.2.14. Insertion Sequence (IS)-Based PCR. One potential disadvantage of PCR tests based on cross-species, widely distributed repetitive elements like ERIC and BOX, is the possibility for a nonspecific amplification when DNA from one organism is contaminated with DNA from another. In some bacterial species, this potential problem can be overcome by techniques that target repetitive elements that are unique to the species.

Bacterial organisms carry certain genetic elements that "jump", translocate, or transpose to new locations in the chromosome. Transposable elements that carry no genetic information except that needed by the elements to insert themselves into a new site are called simple transposons or insertion sequences (IS). Some insertion sequences are

found across species while others are species specific. If the copy number of an IS element in a bacterial strain is high enough and if it is randomly distributed in the chromosome, DNA sequences between these elements can be amplified, as described in repetitive element PCR assays above.

One example of a widely targeted IS element used to type a bacterial organism is IS*6110* of *M. tuberculosis*. IS*6110* is an IS unique to the members of the *M. tuberculosis* complex (*M. tuberculosis*, *M. bovis, M. microti*, and *M. africanum*). IS*6110* has been used as a target as well as a probe for RFLP-Southern blot fingerprint analysis of *M. tuberculosis* strains. Ross and Dwyer reported a PCR-based method designed to amplify sequences between IS*6110* elements to generate DNA fingerprint patterns.[49]

Of course, for IS*6110*-PCR-based typing method to work, the IS element has to be present in large numbers in *M. tuberculosis*. Thus, methods that take advantage of other different interspersed short repetitive DNA elements present in *M. tuberculosis* have been developed. There are at least four such short repetitive elements used to perform PCR-based genotyping of *M. tuberculosis*—(1) the polymorphic GC-rich tandem repeat sequence (PGRS), (2) the major polymorphic tandem repeat (MPTR) loci, (3) the exact tandem repeat (ETR) loci, and (4) the direct repeat (DR) elements located at a single locus in *M. tuberculosis* complex strains (Table 1).

PGRS elements together with IS*6110* were exploited for a PCR-based typing of *M. tuberculosis* strains by a method called double-repetitive-element (DRE) PCR.[50] The greater number of repetitive elements represented by PGRS and IS*6110* increases the chance of amplifying sequences between these elements. When the DRE-PCR method was compared to the standardized IS*6110* RFLP analysis of *M. tuberculosis* strains during a TB outbreak in a prison in Havana, Cuba, the two methods identified the same clusters of TB patients who were clearly linked epidemiologically in the prison, which validated the PCR-based test for epidemiologic application.[51]

Like most PCR-based genotyping tests, the DRE-PCR test suffers from low reproducibility. However, because of its simplicity, the DRE-PCR assay may be useful for screening a large number of isolates prior to using a more labor-intensive but discriminating test such as IS*6110*-RFLP.

The variable numbers of tandem repeats (VNTR) found in the MPTR and ETR loci in *M. tuberculosis* have also been exploited to type this pathogen.[52–54] In *M. tuberculosis*,the MPTR contains 15-bp repeats with a single consensus sequence and high sequence variability between these repeats.[55, 56] Each ETR locus contains large tandem repeats with identical repeat DNA sequences and each locus has a unique repeat sequence.[53] Thus, the number of these repeat units at each MPTR or ETR locus can be predicted from the size of the PCR products, which becomes the basis for VNTR genotyping. VNTR genotyping has been applied to a variety of bacterial organisms.[57–59] A recent variant of this method applied to type *M. tuberculosis* is called mycobacterial interspersed repetitive unit (MIRU) VNTR, which is based on *microsatellite*-like sequences scattered throughout the *M. tuberculosis* chromosome.[60, 61] By using 12 of these MIRU loci, several investigators have demonstrated that the resolution achieved by this typing method is comparable to that of IS*6110*-RFLP typing method.[62–64]

Another PCR-based method used to type *M. tuberculosis* is based on a region called direct repeat (DR) locus. This locus contains multiple copies of a repeat 36 bp sequence interspersed with unique spacer sequences which are 34–41 bp long.[55, 65] A typing method based on this variation in the spacer sequences is called spoligotyping (spacer oligotyping).[66] Oligonucleotides representing the spacers are synthetically made and covalently attached to a piece of membrane. This membrane then is used as a target for hybridization against PCR products obtained from amplification of the spacer sequences located between the DRs. PCR products used as probes are generated from the total genome of a strain of *M. tuberculosis* by one set of primers designed to amplify spaces between the DRs in the test strain. If the membrane contains an oligonucleotide representing a spacer sequence also present in the test strain, an amplified product will hybridize to it. This will generate a hybridization matrix, not unlike the microarray discussed earlier. Thus, unlike the previously described PCR-based typing methods, the patterns that are generated and compared are not electrophoretic fingerprints.

One important advantage of spoligotyping over the standardized IS*6110*-based method[14] is that it reliably differentiates *M. tuberculosis* from *M. bovis*, two members of the *M. tuberculosis* complex.[66] This is because of the low copy number of IS*6110* in *M. bovis*. Discrimination of clinical isolates of *M. tuberculosis* by spoligotyping followed by DRE-PCR performed in French West Indies has been found to be almost as discriminating as the reference IS*6110*-RFLP method.[67] The spoligotyping membrane is commercially available. Thus, any laboratory capable of performing PCR should be able to characterize *M. tuberculosis* isolates by spoligotyping.

3.2.15. Multilocus Sequence Typing (MLST). Many other PCR-based genotyping methods for bacterial pathogens have been described. They all use variations of the general theme described above (Table 1). One relatively new method called multilocus sequence typing (MLST) combines PCR assay with sequencing to assign a sequence type designation to a strain. Standardized MLST analysis

for most bacterial organisms is based on sequencing a PCR-amplified region from each of a set of unlinked housekeeping genes. For example, with *S. aureus*, these genes include seven genes: *arcC, aroE, glpF, gmk, pta, tpi*, and *yqiL.*[68,69] Each of the amplified segments from these genes shows potential allelic variation in different *S. aureus* isolates. An MLST clone that is designated as a particular sequence type (ST) is defined as a strain belonging to a set of isolates with identical sequences at each of the seven loci. A methicillin-resistant *S. aureus* (MRSA) strain designated ST8 (also called PFGE type USA300) has recently been reported to cause widespread community outbreaks of severe skin and deep tissue infections in different regions of the United States.[70, 71] Because this is a sequence-based method, it is highly reproducible across different laboratories, and thus standardized protocols have been developed for several bacterial organisms. Protocols as well as ST designations for these organisms are maintained and accessible at http://www.mlst.net.

4. Epidemiologic Problems Addressed by Genotyping Techniques

At least six common epidemiologic concerns related to bacterial infectious diseases are addressed by genotyping tests. They are (1) characterizing distribution and dynamics of disease transmission in geographically widespread areas; (2) identifying and quantifying risk in sporadic occurrence of infectious diseases; (3) stratifying data to refine epidemiologic study designs; (4) distinguishing pathovars from nonpathovars; (5) addressing hospital and institutional infectious disease problems; and (6) identifying genetic determinants of disease transmission. These are discussed separately below.

4.1. Studying Dynamics of Disease Transmission in Geographically Widespread Areas

Much of the literature that applies molecular biology tools to genotype bacterial pathogens addresses this epidemiologic issue—characterizing geographic distribution of clones or clonal groups. Of course, this is an important component of epidemiology, but unfortunately these types of studies are somewhat limited in their ability to provide good understanding of the transmission dynamics of an infectious disease that yields practical solutions to disease prevention and control. Very often, these studies use convenient samples, in which available collection of microorganisms is genotyped first and questions are asked later. A typical question that is asked afterward is "What do we do with the strain type data?" When no other types of data are collected (i.e., demographic characteristics of the human subjects from which the isolates are obtained, exposure measures, clinical features, etc.) the analysis of the isolates is limited to just describing the number of clones, the proportion that each clone contributes to the study collection, speculations about which clone descended from which, and their geographic distribution. Unfortunately, these types of data contribute little to public health.

For molecular epidemiology to be truly relevant, the right questions need to be asked first before any strains are genotyped. Tracking a strain from place to place and over time is one application of molecular biology techniques, but such an application is not sufficient to address important and relevant questions about disease transmission. In infectious disease epidemiology, researchers and practitioners ask the following types of questions[1]: How does an organism get introduced into a community, and how and why does it spread? What are the risk factors for infection and transmission in a community and how is the infection maintained in a community of hosts? How and why does a particular strain suddenly emerge to become the predominant strain in a community, and why does it disappear? How is drug-resistant infectious disease prevalence in a community affected by fluctuations in clonal distribution over time in that community? How is the prevalence of spectrum of clinical manifestations (mortality, severe disease, asymptomatic infection) of an infectious disease affected by clonal distribution of a pathogen in a community? Do unique biologic characteristics of a member of a bacterial species contribute to enhanced transmission and hence increased prevalence of that member in a community or institution? How do we use the knowledge we gain about the dynamics of disease transmission to implement effective disease control programs? How do we measure the effect and impact of the intervention made based on the knowledge acquired from the use of a particular laboratory test? Once these questions are asked, one can then decide how to collect the isolates, which collection of isolates should be genotyped, what comparison isolates (controls) should be collected, and which of the many strain typing techniques should be used.

4.2. Identifying and Quantitating Risk in Sporadic Occurrence of Infectious Diseases

When a disease occurs as part of a recognized outbreak, it is possible to identify vehicles or risk factors for that illness. This is because in an outbreak, an analytical study

(case–control, cross-sectional, or cohort) can be designed to implicate a source or reservoir of an infectious agent responsible for the outbreak. If a risk factor or a vehicle of an outbreak is identified, the number of cases in that outbreak attributable to that risk factor (attributable risk fraction) can be calculated. In an outbreak, this would be 100% minus the background disease prevalence for that place. Unfortunately, in places like the United States, it is estimated from surveillance reports that less than 20% of reported cases of foodborne diseases, such as salmonellosis, come from recognized outbreaks.[72] The others are reported from sporadic cases. It is extremely difficult, if not impossible, to identify risk or estimate attributable risk fraction for sporadic diseases. The ability to genotype bacterial isolates from sporadic disease cases provides an opportunity to identify risks and calculate attributable fractions for those risks. One early example of such a study follows.

In late summer of 1981, case–control studies of two different salmonellosis outbreaks in New Jersey and Pennsylvania caused by *S*. Newport and *S*. Typhimurium implicated precooked roast beef produced at a meat processing plant in Philadelphia as the vehicle.[73] The distribution of the contaminated beef, of course, was not limited to just these two outbreak settings. It was distributed statewide in both New Jersey and Pennsylvania. The question that was asked was, "what proportion of the salmonellosis cases in these two states during this period that were not part of the two recognized outbreaks were caused by consumption of the contaminated precooked roast beef?" That is, the question asked for the proportion of all sporadic cases of salmonellosis in the two states attributable to the contaminated precooked roast beef.

None of the *S. typhimurium* isolates contained any plasmids, so this technique could not be applied to further subtype this *Salmonella* serotype. *S. newport* isolates from the two outbreaks and an isolate from the implicated meat product, however, contained identical 3.7 and 3.4 MDa plasmids.[74] *S. newport* isolates from persons in the two states not involved in the outbreaks were obtained from the respective state health department laboratories from the summer of 1981. In addition, *S*. Newport isolates from the same states before and after this summer were from other states during the same time period (geographic control), was obtained and analyzed. Telephone interviews of the people who got sick during the summer of 1981 revealed that a significantly greater proportion of those infected with a strain containing the 3.7 and 3.4 MDa plasmids ate precooked roast beef shortly before they developed diarrhea.[74] In the summer of 1981, nearly 45% of the *S*. Newport isolates from sporadic cases of salmonellosis in New Jersey and Pennsylvania belonged to this strain. Thus, the fraction of all sporadic *S. Newport* diarrhea cases during this period that could be attributed to this single contaminated product was estimated to be 45%.

This study demonstrated that the incidence of diseases-like salmonellosis in a widespread geographic region could be rapidly and greatly affected by the introduction of a single contaminated food product. In fact, even after recall of the contaminated product, *S*. Newport strains associated with the summer outbreaks were isolated from two persons. It turns out these two cases occurred in siblings of an older child who had acquired the infection during the outbreak period after ingesting the beef.[74] Thus, salmonellosis in a community could be maintained by person-to-person transmission after introduction into that community by a contaminated product. The plasmid profile analysis, thus, helped not only to estimate an attributable fraction of a risk factor but also to describe the dynamics of community transmission of salmonellosis that would have been difficult, if not impossible, to do by conventional epidemiologic methods.

4.3. Stratifying Data to Refine Epidemiologic Study Designs

Stratification of data is one of the most common analytical procedures used in epidemiology to reduce bias after data had already been collected. It helps to determine more precisely an association of an attribute with disease or outcome, controlling for the effects of a larger stratum to which that attribute belongs.[1] Because molecular strain typing methods can group data related to infectious agents by subtypes, the strain subtype information itself can be used to develop a new case definition, which may comprise one stratum.

For example, in a chest clinic in a large city, patients from whom *M. tuberculosis* is isolated would all be grouped as culture-positive tuberculosis (TB) patients. If one were to do a study to identify risk factors for TB, the initial case definition of TB may be patients from whom *M. tuberculosis* is isolated. Here, an analytical study to identify risk factor for TB is likely to identify host-related factors, such as immunosuppression, old age, diabetes, and poverty. However, if the *M. tuberculosis* isolates from different patients can be tested for drug susceptibility, then these TB patients may be reclassified, according to the drug resistance of their isolates. Such TB patients may then be regrouped into two new strata—those with multidrug-resistant TB (MDRTB) and those with drug-susceptible TB. Each patient stratum (MDRTB versus drug-susceptible TB) can then be used to define cases or controls or comparison group in a case–control analysis to identify a new risk factor (e.g., risk for MDRTB). Such an analysis will find risk factors that are more specific than the

risk factors identified for TB above. They may include, for example, previous history of TB treatment.

Then, if the MDRTB *M. tuberculosis* isolates from above are genotyped and the collection of these isolates are found to be comprised of one clone responsible for 40% of that collection, one can then look for risk factors for infection with that clone. Persons infected with that clone may share a common exposure, such as being exposed to a co-worker with TB at an office. The fact that 40% of them belonged to a cluster also suggests that the people infected with this clone were recently exposed and that they did not result from an infection that occurred many years ago.

One reported study illustrates this idea.[75] In the 1970s and 1980s in São Paulo, Brazil, multidrug-resistant strains of *Salmonella* serotype Typhimurium were a common cause of childhood diarrhea as well as meningitis.[76] The sources of these *Salmonella* organisms were unknown. In a multiclinic study of acute diarrhea in children less than 6 years of age in the city in the early 1980s, *Salmonella* were isolated from 40 (11%) of 358 children with diarrhea, 22 of which were *S*. Typhimurium; all were multidrug resistant. A case–control study comparing children infected with *S*. Typhimurium versus other serotypes of *Salmonella* found recent hospitalization to be a risk factor for *S*. Typhimurium infection. In the study, children who came to the study clinics with diarrhea developed diarrhea at home. Children with history of recent hospitalization were previously hospitalized for illnesses such as pneumonia and acute respiratory infections that required antimicrobial drug treatment. Because it was known at that time that recent exposure to penicillins or antimicrobial agents was a risk factor for acquisition of multidrug-resistant salmonellosis,[77] the investigators were faced with the question of whether the children with *S*. Typhimurium salmonellosis got infected at home or during the previous hospitalization.

The investigators examined plasmid profile of the *S*. Typhimurium isolates. They identified four distinct plasmid profiles that accounted for 47% of the 22 isolates (Figure 1). Each profile was found to cluster in time and in a particular hospital in the city. The others spread over a 2-year period in a typical endemic pattern of occurrence. Thus, 47% of the *S*. Typhimurium infections could be traced to particular hospitals in the city.[77] Furthermore, the study showed that what appeared to be an endemic pattern of disease occurrence in a community was actually composed of at least four outbreaks that occurred in hospitals, unrecognized until the isolates were genotyped.

A similar observation was made by a more recent study using PFGE to subtype *S*. Typhimurium isolates from "sporadic" cases of salmonellosis in Minnesota between 1994 and 1998.[78] Of 174 distinct PFGE patterns found among 958 isolates, the investigators detected four large outbreaks in the state that had not been previously recognized.[78] They also identified many multidrug-resistant strains that had been previously described among *S*. Typhimurium isolates obtained by CDC in the 1970s–1980s.

Thus, in the above two examples of salmonellosis, strain typing analyses (plasmid profile or the PFGE strain typing) helped to "unmask" several discrete outbreaks from a background of so-called sporadic or "endemic" cases of salmonellosis in a city and state. Endemic salmonellosis appears to be comprised of many small outbreaks. This is one of the major discoveries about infectious disease epidemiology made in the last 25 years by the application of molecular biology tools. In fact, it challenges the traditional view about infectious disease occurrence and raises a rather provocative suggestion that there is no such thing as endemic salmonellosis; all cases of salmonellosis may actually be part of outbreaks that go undetected because of absence of strain type information.

Thus, as illustrated above, different laboratory tests identified distinct strata, each of which then could be used to define a new group (i.e., new case definition). Then each stratum could be compared against others in a case–control study design to identify a risk factor for one group. Genotyping data provide the most refined stratum, and if the sample size does not get too small, an analysis can be performed to identify a specific risk factor for that stratum. More refined the stratum, more specifically the risk factor for that stratum is identified. Furthermore, stratification by genotyping methods identifies risk factors related to the pathogen itself—specific site of transmission of a specific clone in the example of salmonellosis in São Paulo, Brazil. Thus, genotyping creates an opportunity to do an analytical study that generates a new hypothesis—refines a study design.

Most importantly, from a public health perspective, a study design that can identify risks for a refined stratum can also identify a more focused intervention option. Stratification of cases, for instance, by antibiograms of the case isolates usually identifies host-related factors as risk factors—e.g., previous exposure to antibiotics. This knowledge, while helpful, does not provide a focused intervention option, and often, as we all know, such knowledge does not contribute to long-lasting effective interventions. In the example of salmonellosis in Brazil, however, further stratification of the *Salmonella* isolates by plasmid profile analysis identified a more specific risk factor related to the isolates themselves. The knowledge that many cases of multidrug-resistant salmonellosis were occurring in specific hospitals in the city brought attention to the need to identify factors within the hospitals that contribute to *Salmonella* transmission. Today, nosocomial transmission of multidrug-resistant

salmonellosis in São Paulo is rare. Thus, this ability to create an opportunity to identify specific intervention options is another major contribution to infectious disease epidemiology made by molecular epidemiology. Many examples of such applications are described elsewhere.[1]

4.4. Distinguishing Pathovars from Nonpathovars

E. coli can cause diarrhea, urinary tract infection (UTI), meningitis, septicemia, septic shock, and wound infections. Yet there are *E. coli* strains that colonize our intestine without ever causing disease. Among *E. coli* strains that cause diarrhea, there are several distinct groups, and they differ from those that cause UTI, meningitis, septicemia, and other diseases. Thus, being able to distinguish *E. coli* strains associated with a particular type of disease, and separating them from non-pathogenic variants of *E. coli*, is an important activity in epidemiologic investigation. This way of classifying strains is called virulence or pathogen typing. *E. coli* strains that cause disease are the best examples of human *pathotype* or *pathovar*.

While traditional methods are also available to separate *E. coli* into distinct virulence types, molecular biology techniques have greatly simplified this task. In particular, *E. coli* strains associated with diarrhea have come to be classified into distinct groups (enteropathogenic *E. coli*, enterotoxigenic *E. coli*, enteroinvasive *E. coli*, enterohemorrhagic *E. coli*, shigatoxin-producing *E. coli*, enteroaggregative *E. coli*, diffuse-adherent *E. coli*), based on a unique set of factors that define the group.[79] However, it should be noted that what made possible the attribution of these virulence factors to these groups of *E. coli* is that many of these groups have been recognized to cause outbreaks, either at the community level or in institutional settings.

In obvious outbreaks, it is not necessary to genotype the implicated pathogen to claim that there was an outbreak. In fact, it is the other way around. Outbreaks are used to validate a genotyping test itself. If a particular genotyping method shows that a strain maker is indistinguishable in all the isolates from an outbreak, but that it differs from comparison isolates obtained from sources unrelated to that outbreak, that method is said to be validated for epidemiologic investigation of that organism. That is, the method can be used to study apparent sporadic diseases caused by that organism.

However, there is another group of *E. coli* that causes extraintestinal infections (sometimes referred to as ExPEC, or extraintestinal pathogenic *E. coli*), which are not as obvious as to why they cause disease.[80] That is, it is not clear whether these *E. coli* strains are members of the normal intestinal flora that cause disease only when they happen to enter a sterile niche, such as the blood stream, bladder, CSF, or deep tissue. Unlike the groups of *E. coli* that cause diarrhea, ExPECs do not carry any virulence factors that clearly distinguish them from those strains isolated from the intestine. Unlike diarrheagenic *E. coli*, ExPECs are not usually recognized to be associated with obvious outbreaks. This makes attribution of a clone of ExPEC to disease more difficult.

Thus, with ExPECs, the application of genotyping methods to address their epidemiology uses an approach distinct from that used to study diarrheagenic *E. coli*. A recent set of studies of community-acquired urinary tract infections (UTI) suggest that outbreaks of UTI do occur in community settings.[81–84] Such observation was used by investigators to postulate that some of the multidrug-resistant uropathogenic *E. coli* strains causing UTI in women may have food animal as a reservoir.[81, 85–87]

In diseases such as UTI where an outbreak occurrence is not obvious, a genotyping method itself may provide a clue that an outbreak may have occurred in a community; this observation generates a new hypothesis about disease transmission. The hypothesis, then, can be tested by conducting a case–control or cross-sectional study. For example, with UTI, a study can be performed to see if there is any association between a predominant clonal group of uropathogenic *E. coli* identified by a strain typing method and a risk factor. If so, this would provide evidence that there was indeed an outbreak. Here, the ultimate confirmation of the hypothesis will be made by showing that the removal of that risk factor leads to amelioration of the recognized problem.

Same questions arise in distinguishing organisms that also happen to colonize non-sterile niches of the human host or occur as saprophytes in the environment. Examples of the latter include *S. pneumoniae*, *Helicobacter pylori*, *S. aureus*, and Gram-negative bacteria other than *E. coli*. Approaches similar to those used to study ExPECs can be applied for these organisms.

4.5. Addressing Hospital and Institutional Infectious Disease Problems

Hospital-associated or nosocomial infections are defined elsewhere in this book (See Chapter 26). In developed countries, organisms that are most frequently associated with nosocomial infections are usually members of the "normal" flora in the non-sterile niche of a human host, which include the skin, nasopharynx, and colon, or saprophytic organisms in the hospital environment. The most common such agents of hospital infections include coagulase-negative *Staphylococci, S. aureus, Enterococcus spp., Clostridium difficile, E. coli, Enterobacter spp*., *Klebsiella pneumoniae, Pseudomonas aeruginosa, Acinetobacter spp., Proteus spp.,*

Stenotrophomonas maltophilia, Serratia spp., and *Candida spp*. Non-commensal or non-saprophytic pathogens that cause hospital infections include those transmitted by blood products (e.g., HIV, HBV, HCV, *Yersinia enterocolitica*) and respiratory pathogens (including severe acute respiratory syndrome [SARS]-associated coronavirus). In developing countries infections caused by *M. tuberculosis* and *Salmonella* introduced into a hospital by an index case, staff, visitors, or contaminated food are still common.

Genotyping bacterial organisms isolated in hospital or other institutional settings have become routine in many places, especially in developed countries. In fact, these techniques have become an indispensable part of hospital infection control activities.[88] While probe-based methods are most frequently used to detect drug-resistant organisms to augment clinical management of patients, many hospitals use genotyping tests to support nosocomial infection control practices. Teaching hospitals use genotyping methods to study nosocomial infection epidemiology.

Many of the infectious disease epidemiologic concerns in institutional settings are distinct from those related to field or community settings. While obvious outbreaks do occur in hospitals, very often, clusters of infectious diseases observed in hospitals are difficult to characterize as outbreaks. This is because patients in hospitals have host-related factors (immunosuppression, prolonged antimicrobial drug exposure, underlying illness) that predispose them to infection with "normal flora", saprophytes, or recognized pathogens. The distinction among colonization, contamination, and infection becomes blurred and is a frequent topic of discussion among hospital staff. One important question that arises in these settings, therefore, is, "do these organisms have biologic characteristics that enable them to cause disease or do they cause disease only because of host susceptibility factors?"

Another major area of concern in hospital infections, of course, is the drug-resistant infections. Very often, when risk factor studies for drug-resistant infections in hospitals are carried out, they find host-related factors—antimicrobial drug exposure, old age, underlying medical conditions, prolonged hospital stay, etc. Conventional epidemiologic studies rarely identify factors that can be attributed directly to the organisms themselves—sources or reservoir, transmissibility, and their biologic characteristics that determine disease production versus asymptomatic colonization. Thus, in hospital epidemiology, another important question is, "do antimicrobial drug-resistant microorganisms predominate in hospital settings because they are selected by the use of antimicrobial agents, or do they predominate because of distinct biologic characteristics possessed by a limited number of clonal groups that happen to be drug resistant?" Molecular epidemiologic methods are beginning to address these questions.

Given that normal flora and saprophytes found in hospital settings are comprised of a large number of strain types, one would expect drug selection pressure to generate a large number of drug-resistant strains to cause hospital infections. One of the most intriguing observations made recently about drug-resistant bacterial hospital infections, however, is that, despite strong antimicrobial drug selection pressures, most of these infections are actually caused by a limited set of bacterial strains. Most studies found that drug-resistant strains that are isolated from hospital invasive disease sources are comprised of a limited number of strains. In New York, a 2-year survey of vancomycin-resistant *Enterococcus faecium* (VRE) infections at a teaching hospital found 54 different PFGE subtypes among 182 isolates. One-third of these were accounted for by just two PFGE subtypes.[89] In Tennessee, a similar survey in different hospitals over a 3-year period showed that among 34 different PFGE types, one was responsible for 61% of 106 VRE isolates obtained from seven different hospitals.[90] In Tennessee, the investigators found that the introduction of the predominant PFGE types at different institutions was caused by new patients transferred to these institutions. Thus, these studies suggest that a clonal strain carried by a transfer patient, once introduced into a hospital setting, can rapidly become predominant in that hospital, and that such a mode of transmission is more important than the selective pressures of antimicrobial drugs in establishing a large number of drug-resistant nosocomial infections. Without the genotype data, such a conclusion would be difficult to make. This type of observation also helps to streamline nosocomial infection control practices. In this case, the recommendation based on the observation is to screen transfer patients for VRE before they are sent to a particular ward in the recipient hospital.

The observations described above with VRE apply to other hospital infections, including those caused by methicillin-sensitive (MSSA) or methicillin-resistant *S. aureus* (MRSA), *E. coli*, and other Gram-negative bacteria. It is beyond the scope of this chapter to discuss each of these agents of hospital infection, and the reader is encouraged to refer to reference (1) for further reading.

4.6. Identifying Genetic Determinants of Disease Transmission

The next stage in the evolution of laboratory-based epidemiology is the methodology to identify genetic basis for disease transmission. This, of course, applies to both the host and the pathogen. Host factors that enhance the

likelihood of development of a clinical manifestation after a bacterial infection could also render such hosts possible new sources of transmission to other hosts. Communities with a high prevalence of persons with HIV infection or AIDS facilitate greater likelihood of transmission of tuberculosis, just because of the greater prevalence of cases of tuberculosis. Thus, host genetic factors that have a similar effect on infection could contribute to enhanced transmission of a disease. Studies that examine host genetic factors that affect disease transmission are just beginning.[91] Of course, in addition to host factors, environment can greatly influence infectious disease distribution, including temperature, weather, season, urbanization, industrialization, and socioeconomic conditions. Such influences on disease transmission and epidemiology of infectious diseases require a separate chapter in itself. In this chapter, only pathogen genetic factors that facilitate transmission and therefore disease distribution are dealt with.

As mentioned earlier, one of the common molecular epidemiologic exercises involves attempts to explain over-representation of clones, clonal groups, or clonal complex strains in a community or institutional settings. Many of these can be explained on the basis of epidemiology, such as point-source contamination of a widely distributed food product (as in salmonellosis) or airborne transmission from a single index case (as in tuberculosis). However, we also know of many situations in which there is no obvious explanation for the predominance of one particular strain of a microorganism. Once epidemiologic explanation for the predominance is ruled out, possible biologic bases for this observation needs to be examined.

All pathogens have developed their own distinct strategies to transmit themselves to new hosts within a context of an environmental setting. Studies to date that have attempted to identify a pathogen's specific genetic determinants of transmission have used two different approaches: (1) those that attempt to identify a type of infection in a host that enhances opportunities for transmission to new hosts and (2) those that attempt to identify a unique niche or reservoir that becomes a major source of transmission to human or other animal hosts.

Tuberculosis can arise from an infection that occurred in the remote past (reactivation disease) or from a recent new infection (rapidly progressive disease). As mentioned earlier, over-representation of a particular strain of *M. tuberculosis* in a community could result from recent transmission from a highly infectious index case (e.g., someone with a cavitary lung lesion working in an enclosed space with an opportunity for contact with many others). In a study conducted in the early 1990s in New York City, one drug-susceptible strain of *M. tuberculosis* called "C strain" was found to be responsible for nearly 10% of all newly diagnosed cases of tuberculosis.[92] A series of case–control studies found C strain to be significantly associated with injection drug use. However, there was no obvious epidemiologic relationship among the injection drug users infected with this strain, nor was there any epidemiologic relationship among non-users infected with the same strain. This prompted investigators to look for a biologic basis for the predominance of C strain in New York City.

Ultimately, C strain but none of the other *M. tuberculosis* strains identified in the city was found to be resistant to reactive nitrogen intermediates (RNI) and hydrogen peroxide in vitro.[92] These are effector molecules that *M. tuberculosis* is likely to encounter inside macrophages in a host after infection. It was hypothesized that since injection drug users, who are normally a high-risk group for tuberculosis, regularly inject themselves with a variety of antigens that stimulate their macrophages to express RNI and hydrogen peroxide, such a practice will eventually select for RNI and hydrogen peroxide-resistant strain of *M. tuberculosis* to emerge in that risk group. If such a strain infects a non-user, it will cause a rapidly progressive disease because such a host does not carry macrophages making RNI and hydrogen peroxide, which would otherwise control the initial infection with *M. tuberculosis*. That is, infection/disease ratio increases when one is infected with such a strain. Thus, more people will develop rapidly progressive disease in a community where such a strain is circulating. This would explain the predominance of C strain in New York City. Hence, in this case, a human behavior appears to have selected for a new strain of *M. tuberculosis* that eventually affected the epidemiology of tuberculosis in New York City.

C strain was further studied in the laboratory and ultimately, a gene called *noxR1* was identified that when transferred into RNI-susceptible *E. coli* or *M. smegmatis* strains rendered these hosts resistant to RNI.[93] Subsequently, additional genes that exhibited RNI and hydrogen peroxide resistance were identified,[94, 95] which opened a new area of tuberculosis pathogenesis research—study of the mechanisms of resistance to natural antimicrobial effector molecules elaborated by the human host against *M. tuberculosis*. These genes may not completely explain the mode of transmission and reason for the predominance of *M. tuberculosis* strain in a community, but these are the earliest studies that applied molecular epidemiologic methods to identify a particular clone of a clinical isolate to study its biologic basis for its distribution and occurrence in a community. Here, the over-representation in New York City of an *M. tuberculosis* strain was attributed to this strain's enhanced ability to cause rapidly progressive disease after a new infection. A mechanism by which an *M. tuberculosis* strain can cause rapidly progressive disease was sought; the strain's resistance to macrophage effector molecules was found to be

possibly related to this mechanism. Genes that mediate this phenotype were identified.

The second type of approach used to identify a genetic basis for disease transmission focused on salmonellosis caused by *S. enterica* serotype Enteritidis. *S.* Enteritidis is the most common cause of egg-associated salmonellosis in developed countries. In a study of henhouses in the United States, 18–25% of captured mice were shown to be infected with *S.* Enteritidis, while *S*. Typhimurium was cultured from only 1.5% from the same henhouses.[96] In the same study, chicken eggs contaminated with *S.* Enteritidis were found in 9 (43%) of the 21 henhouses.[96] Unlike the other *Salmonella* serotypes that infect the surface of egg shells, *S*. Enteritidis infect eggs internally.[97] *S.* Enteritidis multiply inside the egg if left at room temperature. Thus, eggs serve as an "amplifier" of transmission to human hosts, which explain the unique epidemiology of salmonellosis caused by this pathogen. Thus, this second approach to identify a genetic basis for disease transmission attempted to look for a biologic mechanism for the establishment of a reservoir for a pathogen that then serves as a major source for human infection. The question, therefore, is, what enables *S*. Enteritidis and not the other *Salmonella* serotypes to survive in the egg?

This question was addressed by Lu et al., who examined multiple clinical isolates of *S*. Enteritidis for susceptibility to chicken egg albumen. They first found that most clinical isolates of *S*. Enteritidis were relatively more resistant to egg albumen than most clinical isolates of *S*. Typhimurium.[98] One *S*. Enteritidis strain that was highly resistant was analyzed further. Lu et al. eventually identified a gene called *yafD* that when transferred into an egg-susceptible strain of *S*. Typhimurium rendered it resistant.[98] Disruption of *yafD*in the original resistant *S*. Enteritidis strain made it more susceptible to egg albumen. The mechanism of resistance to albumen associated with *yafD* is not yet known.

Thus, once again in this example, a molecular epidemiologic approach first identified a clinical strain of *S*. Enteritidis, which when tested further for a distinct phenotype led to the identification of a gene associated with that phenotype. These types of studies should yield new understanding of how infectious disease transmission occurs and should provide novel approaches to disease control and prevention. These are just beginning to be applied in this new phase of molecular epidemiology research.

5. Summary

Molecular epidemiology should not be regarded as just another technique or a tool, but as an established discipline in epidemiology that can advance our knowledge about infectious diseases in ways that were not previously possible. Molecular epidemiology has begun to challenge old notions and reveal new paradigms concerning the epidemiology of infectious diseases. This chapter introduced new concepts that emerged within this discipline and a sample of its applications. The literature is vast and molecular epidemiologic methods are now a major component of most laboratory-based infectious disease epidemiologic studies. However, it is a constantly evolving discipline and should continue to provide new insights into elucidating epidemiology of infectious diseases in the future.

CHAPTER 4

The Epidemiology of Bacterial Resistance to Antimicrobial Agents

Fred C. Tenover and John E. McGowan, Jr.

1. Introduction

Infectious diseases have continually played a role in shaping human history. The plague pandemic of the 13th century claimed approximately 25% of the world's population. Dysentery decimated the forces of Napoleon, and tuberculosis, also known as "the white plague," condemned many of history's most influential leaders, writers, artists, and scientists to untimely deaths, often in their most productive years. Thus, it was assumed that with the introduction of antimicrobial agents into clinical medicine during the 20th century, the conquest of infectious diseases was likely to be close at hand. Yet, a closer examination of the medical literature beginning in the 1940s reveals an ominous trend that would be repeated over and over again throughout the next several decades: The discovery of virtually every new antimicrobial agent effective against bacteria was followed sooner or later by the recognition of bacterial resistance to the agent. How bacteria develop resistance to antimicrobial agents and how resistant microorganisms spread in hospitals, other healthcare settings, and communities will be the focus of this chapter.

Fred C. Tenover • Division of Healthcare Quality Promotion, National Center for the Prevention, Detection, and Control of Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia 30333, USA. **John E. McGowan, Jr.** • Department of Epidemiology, The Rollins School of Public Health of Emory University, Atlanta, Georgia 30322, USA.

2. Historical Background

Even while the wonder drug penicillin was making headlines by providing dramatic cures for patients with puerperal sepsis, gonorrhea, and other illnesses, strains showing resistance to the drug were already becoming apparent. Both gram-negative and gram-positive bacteria contained enzymes capable of hydrolyzing penicillin and destroying its antibacterial action.[1,2] Similarly, although the mechanisms of resistance were not understood in the 1940s and early 1950s, physicians treating patients with either of the new antituberculosis drugs, para-aminosalicylic acid or streptomycin, noted that after initial signs of improvement, some of their patients began to deteriorate clinically. The *Mycobacterium tuberculosis* strains recovered from the patients who failed therapy were now resistant in vitro to the antimicrobial agents they were given; this problem persists today.[3] Today, there are no antimicrobial agents used in human medicine for which resistance in at least one target organism has not been recognized.

The paradigm for antibacterial agents is that resistance follows use, and widespread use or misuse of a drug will eventually lead to its loss of effectiveness for treating human illness.[4,5] In some cases, resistance appears quickly. For example, resistance to the semisynthetic drug methicillin developed in *Staphylococcus aureus* just a few years after its introduction.[6] However, for other drug–organism combinations, such as vancomycin and *Enterococcus faecium*, almost 30 years passed between the introduction of the drug into human use and the emergence of resistance.[7] The reasons for the differences in time frames are unclear and probably multifactorial. Yet, the ability of bacteria to circumvent the

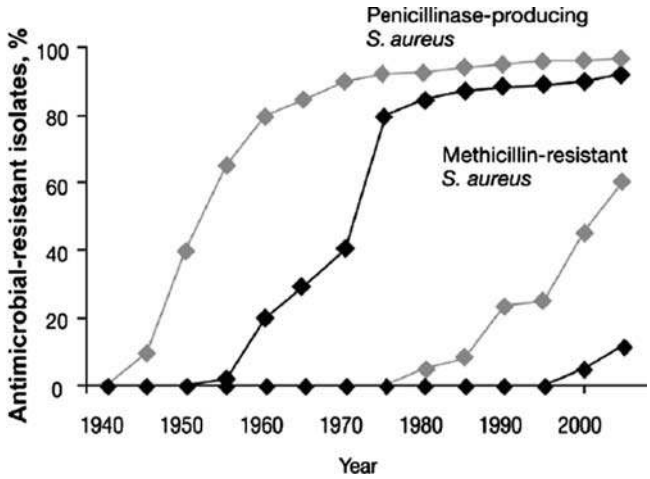

Figure 1. Evolution of antimicrobial-resistant *Staphylococcus aureus* as a cause of nosocomial and then community-acquired infections [5–7]. *Black squares,* nosocomial infection; *gray squares,* community-acquired infection. [From reference[9]]

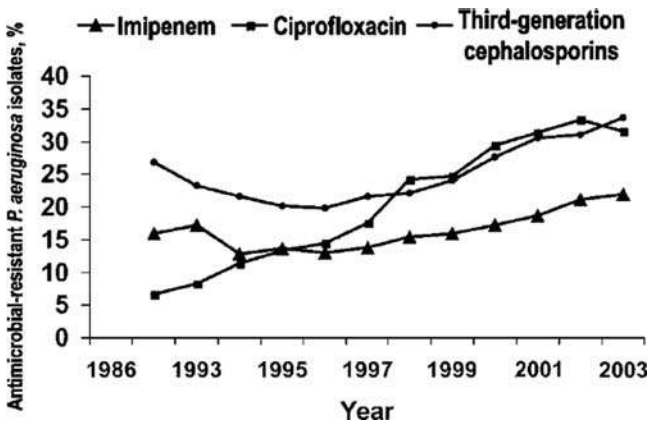

Figure 2. Resistance to antimicrobials (imipenem, ciprofloxacin, and third-generation cephalosporins) in *Pseudomonas aeruginosa* isolates recovered from intensive care unit patients (National Nosocomial Infections Surveillance System, unpublished data). [From reference[9]]

killing action of antimicrobial agents has clearly impeded our ability to treat individual patients and to control large outbreaks of infectious diseases.[8] Examples of emerging antimicrobial-resistance problems that have developed during the last two decades are given in Figures 1 and 2.[9]

2.1. Importance of Changes in Resistance Epidemiology

The continual spread and changing patterns of antimicrobial resistance in bacteria are of concern to clinicians and epidemiologists alike.[10,11] The increase in bacteria that are resistant to frequently used anti-infective agents is well documented.[9,12] Some health-care-associated organisms are resistant to all commonly used antimicrobial agents.[13,14] Whereas resistant bacteria were previously common only in intensive care units of hospitals, these health-care-related organisms more recently have been recovered from non-intensive care hospital inpatient areas and are now isolated with increasing frequency in extended care facilities, ambulatory surgical units, home health-care sites and other health-care settings.[15,16] Resistance also remains important in the "community" setting, that is, in situations where the victim has had no contact with health-care institutions.[17] To complicate matters even further, resistant organisms that arise in the community are now also spreading into health-care settings.[18,19]

3. Mechanisms of Resistance

3.1. Intrinsic Resistance

Some bacteria are intrinsically resistant to antimicrobial agents because (1) they lack the target site for that drug, (2) the drug is unable to reach the site of action, or (3) the organism contains a chromosomally encoded resistance mechanism (Table 1). For example, most gram-negative organisms are resistant to vancomycin because this large, hydrophobic drug cannot penetrate the organism's cell membrane.[20] Thus, these organisms are intrinsically resistant due to a permeability factor. By contrast, *Klebsiella pneumoniae* strains are resistant to ampicillin and other penicillins because these organisms contain a chromosomal β-lactamase that inactivates these and similar drugs.[21] Thus, intrinsic resistance may be due to a number of different mechanisms.

3.2. Acquired Resistance

Bacteria that are by nature susceptible to an antimicrobial agent may become resistant by chromosomal mutation or by the acquisition of new genetic material that encodes the proteins responsible for the resistance phenotype. Chromosomal mutations that occur within the genes that encode the target sites for antimicrobial agents may change the structure of the proteins enough to prevent binding of the drug. Streptomycin resistance in *M. tuberculosis* is a good example of this.[22] Furthermore, the accumulation of point mutations in several different key genes in *M. tuberculosis* under the selective pressure of inadequate antimicrobial therapy (often a result of patients not consistently taking their medications) probably resulted in the multidrug-resistant strains of tuberculosis that caused outbreaks in several large cities in the United States in the early 1990s.[23] Similar reasons

Table 1. Examples of Bacterial Mechanisms of Antimicrobial Resistance

Antimicrobial class	Example	Mechanism	Organisms
Aminoglycosides	Gentamicin	Drug modification	Enterobacteriaceae *Pseudomonas* Enterococci Staphylococci
	Amikacin	Reduced permeability	*Pseudomonas*
β-Lactam drugs	Penicillin	β-Lactamase	Staphylococci Enterococci Enterobacteriaceae *Pseudomonas* Gonococci
β-Lactam drugs	Penicillin	Altered cell wall	Pneumococci Meningococci
Fluoroquinolones	Ciprofloxacin	Altered DNA gyrase	Staphylococci *Pseudomonas* Enterobacteriaceae
Glycopeptides	Vancomycin	Altered DNA ligase	Enterococci
Macrolides	Erythromycin	RNA methylase	Staphylococci Pneumococci Streptococci
Tetracyclines	Doxycycline	Drug efflux	Streptococci Enterobacteriaceae Staphylococci *Pseudomonas*
Trimethoprim	Trimethoprim	Altered enzymes	Enterobacteriaceae *Pseudomonas*

Adapted from Neu.[20]

probably underlie the current prevalence of *M. tuberculosis* strains labeled XDR (extremely drug resistant).[3]

3.3. Molecular Mechanisms

Understanding the acquisition of resistance by bacteria requires consideration of the general pathways for appearance or spread of resistant bacteria in health-care and community settings, and an examination of the molecular mechanisms at work. Several resistance mechanisms have had a major impact on the resistance of gram-positive hospital organisms including new dihydrofolate reductases, novel changes in penicillin-binding proteins, mutations in topoisomerase genes, variants of aminoglycoside-modifying enzymes (which have become widely prevalent in enterococci), and new enzymes that alter cell wall composition.[24,25] These arise from duplication and diversification of existing genes, acquisition of new genes from other organisms, and mutation of acquired genes. The ability of pathogenic bacteria to acquire and disseminate these resistance determinants is orchestrated by a variety of plasmids, bacteriophages, transposons, and integrons.[24]

3.4. Epidemiologic Pathways

On a larger scale, several pathways have been described for appearance or spread of resistance in bacteria.[26] Each of these pathways can be associated with factors increasing risk of developing resistance[27] (Table 2). Recent investigations have highlighted the role of these pathways in clinical practice.

3.4.1. Introduction from Outside. New strains can be brought into a new setting from an outside source by way of a patient, a carrier, or a contaminated commercial product. For example, introduction of resistant strains into hospitals from nursing homes and extended care facilities, as well as transfer in the opposite direction from hospital to nursing home, has become common for certain pathogens.[28] Likewise, methicillin-resistant strains of *S. aureus* (MRSA) that have arisen in the community now have become prevalent in the hospital setting as well.[19]

3.4.2. Exchange of Resistance Determinants. Resistance can be acquired by a previously susceptible strain from another species or genus.[27] Genetic mutation and transfer of genetic material can produce resistance. Changes in only a few base pairs in chromosomal structural or

Table 2. Introduction and Spread of Antimicrobial Resistance into a New Setting

Problem	Example
Introduction of new resistant organisms from outside sources	MRSA from nursing home patient
Mutation of susceptible endemic organisms that leads to a resistant phenotype	Ciprofloxacin-resistant *P. aeruginosa*
Acquisition of new DNA by susceptible endemic organisms that results in resistance	Vancomycin-resistant enterococci
Emergence of inducible resistance in organism that carry previously silent resistance genes	Ceftazidime-resistant *Enterobacter*
Selection of a resistant population of organisms from a heteroresistant population	Aminoglycoside-resistant *Acinetobacter*
Spread of endemic resistant organism	*Serratia marcescens* in ICUs

Adapted from McGowan and Tenover.[27]

control genes may result in one or more amino acid substitutions in a crucial target (enzyme, cell structure, or cell wall), leading to new resistant strains. The change, although subtle, may inactivate whole groups of antimicrobial agents.[29]

3.4.3. Emergence or Selection. Chromosomal determinants for resistance to a given drug may not be expressed until the organism comes into contact with that antimicrobial agent or similar compounds.[27] When permissive conditions appear (e.g., new antimicrobial agents in use in a hospital or the introduction of new conjugative plasmids into a bacterial species), resistance can be manifested rapidly. For example, multiresistant strains of *Pseudomonas aeruginosa* rapidly emerged in patients in a stepwise fashion after exposure to antipseudomonal antimicrobials, and these strains were associated with adverse outcomes.[30] The trigger for emergence may be the antimicrobial agent to which resistance is directed or to another antimicrobial agent that results in induction or derepression of a determinant (enzyme, etc.) and stimulates resistance to the studied drug as well.[24]

Exposure to a stimulus that inhibits or kills the susceptible majority of a population allows a resistant subset of strains to grow, outcompeting the susceptible organisms. The factor in this selection process usually is the antimicrobial agent to which the subpopulation is resistant, but on occasion nonantimicrobial factors, such as those stimulating activity of reactions like acetylation or glucuronylation, also can provide a selective advantage to organisms. These mechanisms necessitate emphasis on avoiding careless use of antimicrobial agents, which can provide a trigger or stimulus to the development of these types of resistance.[31]

3.4.4. Clonal Dissemination. Organisms can spread in clonal fashion from patient to patient, from one patient to another via a health-care worker (e.g., on the hands of ward personnel), in contaminated commercial products (e.g., antiseptics), on other inanimate objects, or by widespread transfer of genetic material from the initial organism to others.[12,32]

3.4.5. Combinations of Pathways. Any or all of these transmission pathways conceivably may have a role in the appearance or increase of resistant organisms in the acute care setting and other health-care settings, such as the nursing home and ambulatory care unit. Sorting out these multiple and concurrent elements, which leads to the appearance and spread of resistance, is an important but difficult problem.[27]

3.5. Examples of Resistance Mechanisms for Various Classes of Antimicrobial Agents

3.5.1. β-Lactam Agents. Resistance to penicillins, cephalosporins, and carbapenems agents most often results from the presence of enzymes in the bacterial cell (β-lactamases) that hydrolyze the β-lactam ring of the antimicrobial agent, an action that detoxifies the drug.[26] However, β-lactam resistance can also be mediated by changes in the site of action of the drugs, the penicillin-binding proteins (PBPs).[33] This occurs by remodeling of the genes that encode the PBPs through incorporation of foreign DNA acquired by the bacteria most often through transformation. These novel mosaic genes containing DNA from the host organism and DNA acquired from related organisms produce altered, albeit functional, PBPs. The latter mechanism is particularly important in the development of penicillin resistance in *Streptococcus pneumoniae*.[34] Newer beta-lactamases have molecular changes that extend their activity to produce resistance to broad-spectrum beta-lactams like extended-spectrum cephalosporins[35] and carbapenems.[36,37]

3.5.2. Macrolides, Azalides, Lincosamides, and Streptogramins. The macrolides, which include agents such as erythromycin and clarithromycin, and the azalides, such as azithromycin, are commonly administered oral drugs used for the treatment of many bacterial respiratory infections and superficial skin infections. Resistance is due either to inactivation of drug (mediated by erythromycin esterases or phosphorylases), efflux of the drug out of the cell, or by modification of the site of action.[38] The latter mechanism, in which the 23S RNA of the 50S ribosome unit is methylated at a specific adenine residue, which prevents binding of the antimicrobial agent to the ribosome, not only leads to high-level resistance to macrolides but

also affects lincosamides (such as clindamycin) and streptogramins (such as pristinamycin), since all three classes of drugs act by binding to the same site on the bacterial ribosome. The so-called MLS-resistance phenotype (for macrolide–lincosamide–streptogramin) is typically observed in staphylococci and streptococci and is often plasmid mediated, but the genes encoding these enzymes also may be found on transposable elements.

3.5.3. Aminoglycosides. Aminoglycosides are commonly used in conjunction with β-lactam agents to treat serious bacterial infections, such as sepsis and endocarditis, because the two groups of drugs frequently act synergistically. Resistance to aminoglycosides is typically mediated by enzymes that modify the drug, so that uptake into the bacterial cell is impeded. However, efflux of drug out of the bacterial cell and permeability barriers to aminoglycosides are also recognized.[39] There are three types of aminoglycoside-modifying enzymes: those that acetylate, adenylate, or phosphorylate the drug. The number of genes encoding variants of these enzymes within each group is remarkably large and diverse. There is indirect evidence for two unique hypotheses on the origin of these resistance genes.[40] On the one hand, several of the genes are similar to those found in soil bacteria that produce antibiotics that protect the host organism from self-inhibition. The DNA encoding these genes may have been released into the soil through cell lysis and picked up by other bacteria, which in turn may have incorporated the DNA into a resident plasmid, allowing it to be mobilized to other bacterial species. An alternate hypothesis suggests that the proteins that modify the aminoglycosides have evolved from similar types of enzymes that have cellular "housekeeping" functions, such as phosphorylation of proteins to activate or inactivate enzymatic pathways.[40] These housekeeping enzymes became adapted over time to inactivation of aminoglycosides under the selective pressure of the presence of the antibiotics produced by other organisms in soil or in the hospital environment. Whether recruited from antibiotic-producing organisms or from other bacterial pathways, the array of aminoglycoside-resistance genes discovered to date is very diverse. The most recent example of this is the AAC(6')-Ib-cr acetylating enzyme that also inactivated ciprofloxacin and other fluoroquinolones that have a piperazine ring.[29]

3.5.4. Tetracycline. Tetracyclines are oral drugs that are frequently used for treating patients with a wide variety of community-acquired infections, including skin infections, Rocky Mountain spotted fever, and chlamydia. Resistance is mediated both by actively pumping of the drug out of the bacterial cell before it can reach its site of action and by target site alteration.[41] Tetracycline-resistance genes are frequently located on plasmids and transposable elements, which enhances their ability to disseminate throughout diverse species of bacteria. There are over a dozen such resistance genes that are divided into several subgroups based on DNA sequence and mechanism. Tetracycline-resistance genes are frequently found on genetic elements with other resistance genes, such as those mediating resistance to chloramphenicol. Many tetracycline-resistance mechanisms are not active against tigecycline, a new minocycline derivative.[42]

3.5.5. Trimethoprim and Sulfonamides. Trimethoprim and the sulfa drugs both inhibit the enzymatic pathway that synthesizes dihydrofolate.[43] Resistance is frequently the result of a plasmid-encoded enzyme that substitutes for a chromosomal enzyme normally inhibited by these drugs. Sulfonamides work through competitive inhibition of the enzyme dihydropteroate synthetase. The plasmid-encoded enzyme is smaller and more heat sensitive and requires a thousand times as much sulfonamide to inhibit it as does the chromosomal enzyme. Similarly, some strains resistant to high levels of trimethoprim, an agent that inhibits dihydrofolate reductase, contain a plasmid-mediated gene coding for a new trimethoprim-resistant dihydrofolate reductase. In each instance, the plasmids provide a mechanism whereby products vital to the bacterial cell can be synthesized and the inhibiting effect of the drug is bypassed.

3.5.6. Glycopeptides. Glycopeptide resistance can be mediated by a series of genes that effectively remodel the cell wall of an organism by altering the normal D-ala–D-ala binding site of vancomycin to D-ala–D-lac or D-ala–D-ser through introduction of an altered ligase enzyme (e.g., *vanA*).[44] The family of acquired vancomycin-resistance genes now includes *vanA*, *vanB*, *vanD*, *vanE,* and *vanG*.[45] The *vanA*-resistance determinant has been recognized among enterococci and *S. aureus* isolates, the latter due to acquisition of a transposon, Tn*1545* and its variants. A second mechanism of resistance noted among glycopeptide-intermediate *S. aureus* (GISA) strains is the thickening of the cell wall in conjunction with metabolic changes that make *S. aureus* isolates no longer susceptible to glycopeptides.[46,47] Such strains with reduced susceptibility to glycopeptides cannot be detected in the clinical laboratory using disk diffusion.[48]

3.5.7. Fluoroquinolones. Fluoroquinolone antimicrobials have been available worldwide for more than a decade.[49] Their widespread use has led to increasing prevalence of resistance to these drugs in most parts of the world. Resistance to fluoroquinolones typically arises by alterations in the target enzymes (DNA gyrase and topoisomerase IV) and through changes in drug entry and efflux.[50] Recent discovery of plasmid-mediated horizontally transferable genes encoding quinolone resistance (e.g., *qnrA*, *qnrB*,

and *qnrS*) perhaps explains some of the rapid emergence of resistance to these drugs.[51] Likewise, AAC(6')-Ib-cr, a variant aminoglycoside acetyltransferase capable of modifying ciprofloxacin and reducing its activity that was mentioned above, also seems to provide low-level quinolone resistance.[29] Each of these mechanisms may facilitate the emergence of higher level quinolones resistance.[51]

3.5.8. Oxalidinones. Resistance to the oxazolidinones, such as linezolid, among staphylococci and enterococci is due to modification of ribosomal RNA often through a G–T substitution at position 2,765.[52,53] Such strains usually have reduced fitness. Fortunately, this genotype is not transmissible to other strains.

3.6. Key Factors in the Development of Resistant Microorganisms

Three factors appear to be critical in the continuing evolution of resistant microorganisms: selection of mutations in common genes that extend their spectrum of resistance, transfer of resistance genes among bacteria, and selective pressures, primarily by antimicrobial use that enhance the development of spread of resistant organisms.[32] Programs for control and prevention of resistance must take heed of these factors.[54]

3.6.1. Selection of Resistant Mutations. The progression of simple β-lactam hydrolyzing enzymes, i.e., penicillinases and first-generation cephalosporinases, to the extended-spectrum β-lactamases (ESBLs), which hydrolyze not only penicillin-type drugs and first-generation cephalosporins, but extended-spectrum cephalosporins (such as cefotaxime, ceftriaxone, and ceftazidime) and monobactams (such as aztreonam), is an example of extending the phenotype of already existing resistance genes.[35] Such ESBL enzymes were first recognized among isolates of *K. pneumoniae* in Germany in 1982.[55] Mutations in the gene encoding the TEM-1 β-lactamase (named after the initials of the patient from whom the first ampicillin-resistant *Escherichia coli* was isolated) led to changes in three amino acids at key points in the enzyme. These changes enabled the active site of the enzyme to accommodate the much larger expanded-spectrum cephalosporins, which resulted in their inactivation. Further investigations of TEM β-lactamase mutants and of the mutants of a related β-lactamase, the SHV family of enzymes, have shown that even a single amino acid change can result in some ESBL activity.[26] The ESBLs now include variations of CTX-M enzymes (a group of cephalosporinase enzymes that hydrolyze the drug cefotaxime more rapidly than they do the drug ceftazidime). The presence of such enzymes in the United States and Europe appears to be increasing.[26]

3.6.2. Genetic Exchange Among Bacteria. Genetic exchange may occur by transformation, conjugation, or bacteriophage-mediated transduction.[40,56] For example, conjugal transfer of the staphylococcal β-lactamase[57] and aminoglycoside-resistance genes[58] to enterococci led to development of multiply-resistant strains that have proven very difficult to treat, particularly when coupled with vancomycin resistance.[16] Vancomycin-resistant enterococci, in turn, have become a significant problem in the United States, particularly in hospital intensive care units.[9] Six vancomycin-resistant *S. aureus* isolates have been recognized in the United States (CDC unpublished observations). The breadth of the genetic exchange network among microorganisms is only beginning to be understood.

3.6.3. Selective Pressure Arising from Antimicrobial Use. The final factor in the evolution of resistance is the broadening of the selective pressure in health-care and community settings that facilitates the emergence of resistance. The term *selective pressure* refers to the environment created through the use of antimicrobial agents that enhances the ability of an organism that becomes resistant by mutation or through acquisition of new DNA to survive and proliferate. Although resistance is not confined to hospital strains, the hospital has often been viewed as an important developing ground of resistant bacteria due to the extensive use of antimicrobial agents in this setting.[27] In addition to extensive use of antimicrobials in humans, the extensive use of antimicrobial agents among children for ear and respiratory infections,[59] and the widespread use of antimicrobial agents in agriculture and animal husbandry,[60] have enhanced development of novel resistance patterns in a variety of pathogenic bacteria in the community setting as well as in the hospital. Although the use of antimicrobial agents as feed additives have been banned in Europe,[61] the practice continues in the United States, South America, and other parts of the world.[62]

3.7. Mechanisms of Gene Dissemination

A key factor in the spread of resistance is the movement of genetic elements independent of the spread of bacterial strains. Figure 3 shows the ways in which an organism may become resistant to antimicrobial agents.[27]

Plasmids are extrachromosomal pieces of DNA that are not necessary for cell survival, but often give organisms a selective advantage to enhance survival. Plasmids may carry antimicrobial-resistance genes, and those plasmids may or may not be self-transmissible to other organisms via conjugation. Small, nontransmissible plasmids may still be mobilized to a bacterial recipient by larger conjugal plasmids present in the same cell. The transfer of

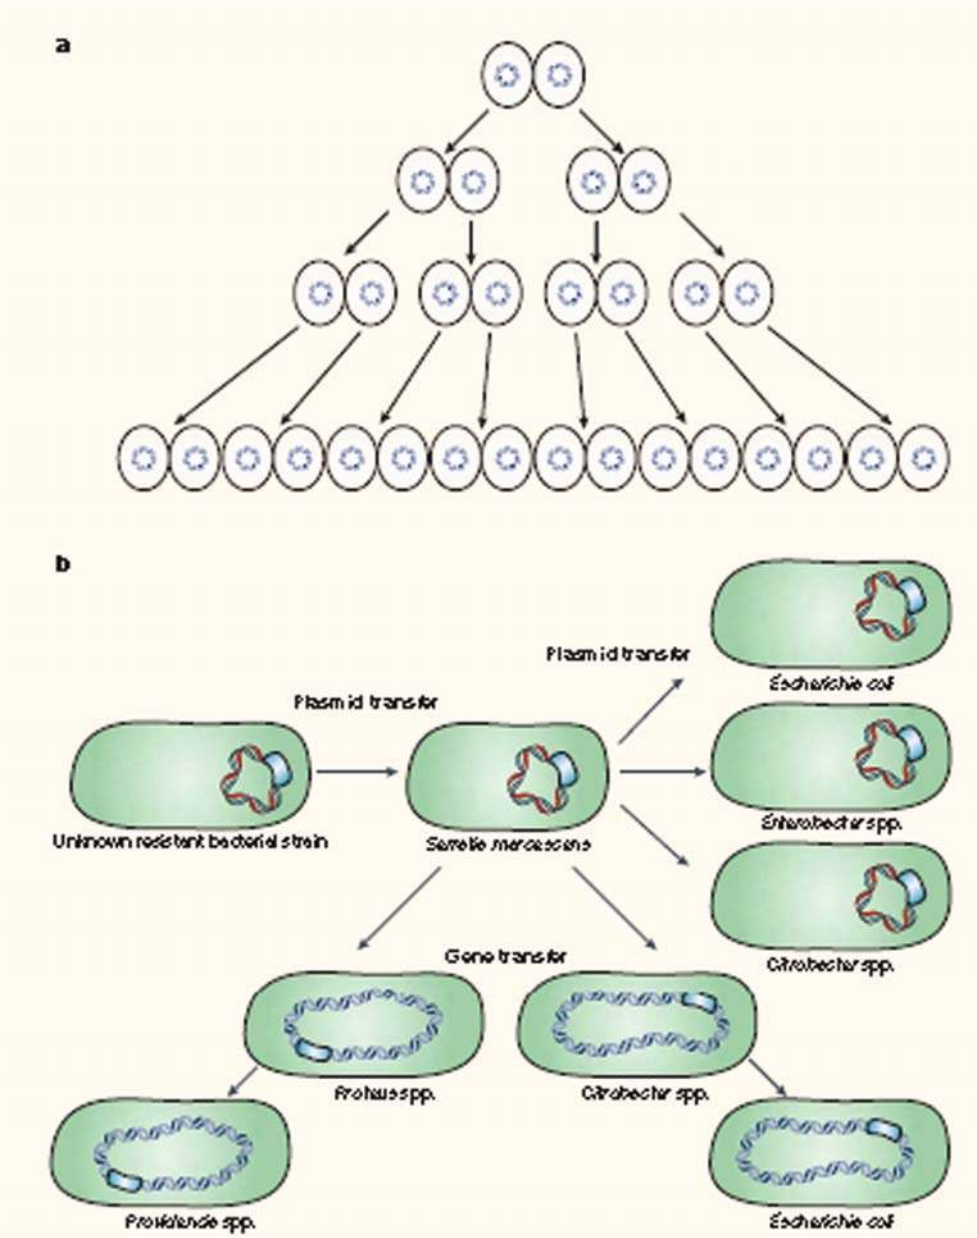

Figure 3. Mechanisms of spread of bacterial resistance. **A** Dissemination of vancomycin-resistant enterococcus carrying the *vanA* resistance gene on a plasmid (*inside circle*). This represents clonal spread of an organism in a hospital. **B** Dissemination of an aminoglycoside-resistance gene (indicated as *bar* on circular plasmid) by spread of the resistant strain, spread of the plasmid containing the gene, and spread of the gene on a transposable element. The plasmid containing the resistance gene was introduced from an unknown strain into an isolate of *Serratia marcescens,* which disseminated and spread among patients in the hospital. The plasmid then transferred to other members of the Enterobacteriaceae (*E. coli*, *Enterobacter,* and *Citrobacter*) via conjugation, followed by transposition of the resistance gene to other plasmids in *Proteus* and *Citrobacter*. The new plasmids containing the resistance gene were then transferred via conjugation to *Providencia* and other strains of *E. coli.* [From reference[27]]

resistance genes via plasmids was first noted in the 1950s by Japanese researchers who reported transfer of a multidrug-resistance phenotype from *Shigella* species to *E. coli*.[63] Plasmids have been reported to mediate resistance to as many as 12 antimicrobial agents,[64] and many plasmids are capable of being maintained by enteric bacilli, pseudomonads, vibrios, and other gram-negative organisms. One particular multiresistance plasmid, pLST1000, was isolated from

gram-negative pathogens in several US cities and from isolates from Venezuela. The mode of intercontinental transmission was not apparent, but the stability of the plasmid over time was remarkable.[65]

As the phenomenon of plasmid transfer among microorganisms was emerging, another genetic element was recognized in gram-negative organisms—the transposon. This genetic element, which was capable of moving from replicon to replicon, such as plasmid to chromosome or vice versa, moved independently of the typical functions of generalized recombination. One family of transposons, those similar to Tn*21*, were found in a variety of multiply-resistant enteric organisms in the late 1970s and 1980s.[66] Later, a set of genetic elements with a very similar structure was discovered in gram-positive organisms, but these elements were conjugal, i.e., the elements were able to move from organism to organism via cell-to-cell contact.[67] These conjugal transposons were observed first in pneumococci[68] and later in *Bacteroides fragilis*.[69] Since pneumococci, in particular, do not maintain plasmids, conjugal transposons probably played a major role in the development of multiresistance in this species. Conjugal transposons apparently require cell-to-cell contact and probably transfer via formation of a circular intermediate form.[67] Together with integrons, the elements into which resistance gene cassettes can enter with relative ease,[70] these elements serve to enhance the ability of resistance determinants to disseminate throughout bacterial populations at a rate much faster and more efficient than could dissemination via plasmids alone.

4. Epidemiology of Antimicrobial Resistance

Studying the epidemiology of bacterial drug resistance has become more of a challenge over the past 20 years as organisms have developed multidrug resistance and the genes encoding resistance have apparently become more mobile. However, newer molecular strain-typing techniques have enabled us to assemble a clearer picture of this process. [27]

4.1. Resistance in Health Care Contrasted with Community Settings

The acquisition of a bacterial pathogen can occur in the health-care setting or in the community, although the two ecosystems are closely linked.[19,27] Those infections that first occur in patients who have been a resident inside a hospital for more than 48 h are called health care associated, while other infections are deemed to be community associated.

For many bacteria that cause health-care-associated infections, the prevalence of resistant isolates varies by location in the institution (for example, between intensive care units (ICU) and non-ICU areas in hospitals)[71,72] (Figure 1). Patterns of resistance in *S. aureus* illustrate this point—data from Project ICARE, a cooperative surveillance effort in about 40 hospitals around the United States, show differences in the prevalence of MRSA isolates from ICU and non-ICU settings. It also has shown an increasing prevalence of MRSA in both ICU and non-ICU hospital areas during three time periods surveyed between 1996 and 2002[73,74] (Figure 2). The prevalence of resistance to selected antimicrobial agents in gram-negative aerobic bacilli also varies by health-care unit.[75] For example, the prevalence of resistance to third-generation cephalosporins in several gram-negative bacilli has increased dramatically throughout the United States in recent years[9] (Figure 3). Similar increases in resistance have also been documented among patients outside the hospital setting.[17] However, among community-associated infections, some still have links back to health-care settings such as with patients who have indwelling catheters or receive dialysis, or those who have been in a health-care facility in the last year.[76]

4.2. New Challenges Related to Resistance Epidemiology

The emergence of resistant bacteria has taken place over several decades. However, in the past 10 years, new facets of clinical resistance have emerged which have led to new challenges for microbiology service providers.

4.2.1. Alteration of Antimicrobial Use Patterns. The emergence of new patterns of antimicrobial resistance can alter the use of antimicrobial agents. For example, the emergence of vancomycin-intermediate *S. aureus* (VISA) strains (originally defined as strains with vancomycin minimal inhibitory concentration (MIC) of 8–16 μg/ml)—which were first detected in patients in Japan and then in the United States—was followed by reports of the isolation of two strains of vancomycin-resistant *S. aureus* (VRSA; MIC $\geq$32 μg/ml) from two different areas of the United States.[77–79] Detection of both VISA and VRSA strains has proved difficult in clinical laboratories using automated methods[80,81] because changes that lead to increased MICs are not readily detected by the analyses and interpretation algorithms that are used in many automated systems. If resistance to vancomycin among staphylococci continues to develop and spread, the use of vancomycin, which has long been considered the mainstay for the treatment of MRSA, could be severely compromised. Fortunately, other chemical

compounds now have been approved for use against MRSA, such as linezolid and daptomycin, and others are in later stages of clinical trials, or earlier stages of clinical development.[82]

4.2.2. Interference with Effective Treatment. During the past decade, strains of *Acinetobacter baumanii* and *P. aeruginosa* have arisen that are resistant to all the antimicrobial agents that are usually tested.[13] These organisms have become important hospital pathogens, especially in patients with hospital-onset pneumonia, so loss of the usual antimicrobial agents for treatment can dramatically interfere with patient care.[83,84] Increasing resistance in these organisms has resulted in treatment of patients with drugs such as colistin and polymyxin B, which were essentially abandoned in the 1970s because of their unacceptable levels of toxicity compared with alternative antimicrobial agents.[85,86] Unfortunately, few laboratories now have the capability to test whether organisms are susceptible to both these older antimicrobials, because appropriate testing materials are not widely available and the interpretation of test results is not straightforward.

Resistance to several different classes of antimicrobial agents continues to develop in organisms, such as *Acinetobacter*, with clinically significant, but difficult to detect, resistance phenotypes.[87] This trend fuels the demand for reliable, practical, and cost-effective detection methods for identifying strains that show new resistance patterns.

4.2.3. Complexity of Diagnosis. New patterns of antibacterial resistance can be quite difficult to detect.[88] This makes it necessary to develop new screening methods for detection of organisms like VISA, VRSA, and those containing ESBLs that are both practical and affordable for clinical and public-health laboratories.

The emergence of bacterial strains that are resistant to routine therapies increases the need for susceptibility testing of alternative therapeutic agents.[8] For example, routine testing of linezolid, quinupristin/dalfopristin, and daptomycin now is needed in areas where prevalence of VISA or VRSA strains is high, routine testing of colistin or polymyxin B might be added when *A. baumanii* strains are resistant to aminoglycosides, beta-lactam inhibitor combinations, and carbapenems.[87] When resistance precludes the use of standard drugs it can also increase the need for testing susceptibility to investigational drugs (that is, those that are not yet licensed in a given country or community), such as testing of MRSA or vancomycin-resistant enterococci (VRE) against dalbavancin.[89]

4.2.4. Altering Requirements for Surveillance. In addition to these local variations, changes in resistance patterns can affect whole cities, regions, or countries, and some changes are evident across national boundaries.[12,90] The appearance of VRE infections has been reported from such diverse parts of the world as North America and Western Australia.[91] This emphasizes the need for reliable surveillance systems that track both health-care-associated and community-based resistance, with local, regional, national, and international scope.[92] However, such systems would need to be standardized and validated to make results comparable.[93]

5. Organisms of Special Importance

5.1. Health-Care-Associated Pathogens

Two health-care-related pathogens continue to be of particular concern: MRSA and vancomycin-resistant enterococci (VRE). In some hospitals, over 70% of the *S. aureus* isolated from inpatients are MRSA,[9] and these strains often are resistant to all licensed drugs except vancomycin, linezolid, daptomycin, and tigecycline.[94] Recently, strains of *S. aureus* completely resistant to vancomycin were isolated from patients in the United States[95] further complicating therapy.[96] MRSA have become highly endemic in many hospitals, and in the community as well, which makes tracking of outbreaks more difficult. Once introduced into a hospital, this organism is very difficult to eradicate.[97,98] Problems with eradication are also true for vancomycin-resistant strains of *E. faecium*, which are often resistant to all other clinically approved drugs. Vancomycin resistance in enterococci is often plasmid mediated and can be the result of several unique resistance determinants.[99,100] Guidelines from the Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control and Prevention (CDC) and the Society for Healthcare Epidemiology of America[98,101] stress the need for prudent use of antimicrobial agents, effective implementation of infection control in health-care settings, and the requirements for adequate laboratory support of infection control. All are of critical importance to reduce the selective pressure for the emergence of resistant microorganisms. Antibiotic use, particularly of vancomycin and cephalosporins, is frequently a risk factor for developing VRE infections.[102] Programs to promote proper stewardship of antimicrobial use have become frequent in health-care organizations, and guidelines for such programs are being developed by professional societies.[54]

Several species of multiresistant gram-negative organisms also continue to be significant pathogens in hospitals.[103] For example, Enterobacteriaceae resistant to aminoglycosides, β-lactams, chloramphenicol, and trimethoprim–sulfamethoxazole emerged in the late 1970s and have become endemic in a number of hospitals in the

United States.[9] Many of these organisms now manifest resistance to the extended-spectrum cephalosporins as well. However, while strains of *K. pneumoniae* primarily are resistant due to the production of ESBLs, *Enterobacter* species are more likely to have chromosomally encoded enzymes related to the AmpC family of β-lactamases.[35] Transmissible imipenem resistance was noted in *P. aeruginosa* in the late 1980s, and now has become a major concern in several parts of the world.[13] *Acinetobacter* species, especially *A. baumannii*, have caused outbreaks in intensive care settings in selected hospitals,[104] and have been associated with infections in military personnel returning to the United States from the Middle East.[105]

5.2. Community-Acquired Pathogens

Development and spread of resistance in community-acquired bacteria have compromised many established therapeutic regimens for infectious diseases.[17,106] The increase in resistance has resulted from increased world travel where people are exposed to novel microorganisms that they bring back to the home country; greater reliance on foodstuffs, such as fruits and vegetables, from international sources that may be contaminated; and dramatic increases in worldwide antibiotic use. For example, in 2004, outbreaks of dysentery in India were reported that were caused by *Shigella dysentariae* strains resistant to all major drug classes, including the quinolones.[107] These organisms contained a broad array of resistance genes, apparently assembled from a variety of enteric bacteria. Multi-drug resistance in *Salmonella typhi*, the cause of typhoid fever, has also been noted, with decreased susceptibility to the fluoroquinolones, which will further complicate the treatment of typhoid fever because few options are available.[108] Widespread use of fluoroquinolones in hospitals for staphylococcal infections in the early 1990s led to the rapid and dramatic increase in resistance,[83] and this class of drugs has significantly reduced effectiveness in many hospitals for treating staphylococcal infections.[109] The emergence of methicillin-resistant staphylococcal strains centered in the community with different characteristics than those previously encountered were dubbed community-acquired MRSA (CA-MRSA). Such strains now are spreading into health-care settings as well; this complicates treatment and prevention strategies for this common cause of community-acquired skin and soft tissue infections.[15,110] Gram-negative bacilli that are part of endogenous flora, such as *E. coli* and *K. pneumoniae*, are also associated with increasing prevalence of resistance to antimicrobial agents commonly used in community-acquired infections.[111,112] The impact is especially notable in treatment for community-acquired urinary tract infections in women.[113]

Another important community-acquired pathogen, *S. pneumoniae*, is a major cause of meningitis, sepsis, pneumonia, and ear infections in the United States and around the globe.[114] Strains resistant to penicillin, tetracycline, chloramphenicol, and trimethoprim–sulfamethoxazole have now been isolated in the United States[115] and in several areas of the world.[116] In the Atlanta area in 1994, 25% of pneumococcal isolates were no longer susceptible to penicillin and required alternate drugs for therapy of serious infections.[117] Other strains of pneumococci highly resistant to the extended-spectrum cephalosporins, the drugs of choice for treatment of penicillin-resistant strains, have emerged and appear to be spreading.[118] This has significantly complicated the development of rational plans for treatment of meningitis caused by these strains, and forced inclusion of vancomycin in initial empiric treatment regimens.[119] Pneumococci can spread particularly well among children in day care centers, but pediatric strains of pneumococci are also now found with increasing frequency in adults.[120] Thus, the availability of more effective pneumococcal vaccines that are immunogenic in younger children (especially those $\leq$2 years of age) may play a significant role in controlling the spread of these resistant pathogens.[121,122]

Another community-acquired pathogen that has engendered considerable interest due to its ability to acquire multiresistance is *Neisseria gonorrhoeae*, a sexually transmitted agent that has been epidemic in the world for almost three decades. High-level plasmid-mediated penicillin resistance emerged in *N. gonorrhoeae* in 1976.[123] The β-lactamase gene was similar to one found just 1 year previously in strains of *Haemophilus influenzae*.[124] Today, quinolones are key therapeutics for gonorrhea, and the emergence of resistance to this group of drugs threatens once again our ability to control this epidemic disease.[125]

Community-acquired infections due to *Neisseria meningitidis* continue to occur in epidemic fashion in developing countries and in localized outbreaks in developed countries. A key part of response to the severe disease produced by this organism is vaccination.[126]

6. Unresolved Problems

The unresolved problems of the resistance story are threefold: How to identify new targets for antimicrobial action for which resistance will be slow to develop; how to eliminate the spread of resistance genes located on plasmids and transposons to other organisms; and, most importantly, how to reduce the selective pressure in community and

hospital settings that encourage the development and spread of antimicrobial-resistant microorganisms. Attention to each of these problems will help lessen the impact of antimicrobial resistance on human and animal health and prolong the effectiveness of the antimicrobial agents that we do have.

CHAPTER 5

Anthrax

Philip S. Brachman and Arnold F. Kaufmann

1. Introduction

Anthrax, a zoonotic disease of herbivorous animals transmissible from animals to man, occurs primarily in three forms: cutaneous, inhalational, and gastrointestinal. Meningitis and septicemia occur but are secondary to one of the primary forms; occasionally, cases of anthrax meningitis are reported in which a primary focus is not identified. The etiologic agent is *Bacillus anthracis*, a gram-positive organism that in its spore form can persist in nature for prolonged periods, possibly years. The incidence of anthrax has decreased over the past 70 years, so that currently, human cases are seen only occasionally in the United States, where reporting is probably fairly accurate. Synonyms for anthrax include charbon, malignant pustule, Siberian ulcer, malignant edema, woolsorter's disease, and ragpicker's disease.

2. Historical Background

The earliest description of anthrax is found in the book of Genesis, the fifth plague (1491 BC), which appears to have been anthrax, was described as killing the Egyptians' cattle. There are descriptions of anthrax involving both animals and humans in the early literature of the Hindus and Greeks. Virgil described anthrax during the Roman Empire (70–19 BC). In the 17th century, a pandemic referred to as "the black bane" swept through Europe, causing approximately 60,000 human deaths and many animal deaths. An association between human anthrax and contact with clothing made from wool and hides was reported.

In 1752, Moret more specifically characterized the disease in man, calling it "the malignant pustle." In 1780, Chabert described the disease in animals. The contagious nature of anthrax was noted in 1823 by Barthelemy. The first microscopic description of the organism was written by Delafond in 1838, and the organism was first described in infected animals in 1849 by Pollender. Pasteur discussed anthrax in some of his earlier writings on his germ theory of disease. In 1876, Koch used *B. anthracis* in developing his postulates concerning the relationship between bacteria and the diseases they cause. Greenfield developed an attenuated animal spore vaccine in 1880.[1–3] Pasteur, responding to a serious problem with anthrax in the French livestock industry, developed and field tested in sheep an attenuated spore vaccine in 1881. In 1939, Sterne reported his development of an animal vaccine that is a spore suspension of an avirulent, noncapsulated live strain.[4] This is the animal vaccine currently recommended for use.

Anthrax in the United States was first reported among animals in Louisiana in the early 1700s. Subsequently, sporadic animal cases have been reported from throughout the United States, and epizootics have been reported from the southern portion of the Great Plains states and the northeastern part of the country. The first human case was reported in a cattle tender in Kentucky in 1824.

Occupational anthrax occurred in the mid-1800s in England, where it was known as woolsorter's disease,[1] and in Germany, where it was known as ragpicker's disease. Ragpicker's disease occurred in individuals who handled rags that had been woven from contaminated animal fibers. The increasing problem of woolsorter's disease in England led to the development of a government inquiry committee that correctly identified the problem as being related to imported animal fibers contaminated with *B. anthracis*.[5] Subsequently, in 1921, a formaldehyde disinfecting station was built by the government in Liverpool.[6] All "dangerous" imported

wools and goat hairs were first washed in formaldehyde baths, which successfully reduced contamination of the animal fibers with *B. anthracis*. The occurrence of inhalational anthrax was drastically reduced, so that only sporadic cases have been reported in England since 1922. The disinfecting station continued to such a level that further disinfection with formaldehyde was not deemed necessary or economical.

In the United States, human anthrax cases have been reported from most of the states. Initially, cases were related to animal contact and reflected areas with enzootic and epizootic anthrax, primarily involving cattle and occasionally sheep and horses. As the United States became industrialized, human cases associated with the textile and tanning industries occurred with increasing frequency. In the early 1900s, these cases primarily occurred in the northeastern states. In the 1950s, cases began to occur in southeastern states, reflecting the movement of the industry.

In the 1920s, the annual number of cases reported in the United States ranged from 100 to 200 cases; in the 1950s, from 20 to 50 cases each year; in the 1970s, from 0 to 6 cases each year; in the 1980s and in the 1990s, one case was reported; from 2000 to 2008, 28 cases were reported that includes the 22 cases that resulted from a bioterrorism event associated with the purposeful contamination of mailed letters and subsequent contact with postal facilities or contaminated letters. One subsequent case occurred in a laboratory employee who was working with *B. anthracis* associated with the bioterrorist event. The decrease in cases (excluding the bioterrorist cases) is the result of the use of a human cell-free anthrax vaccine among high-risk industrial groups, decreased utilization of imported potentially contaminated animal products, improved hygiene in industry, and improved animal husbandry. The incidence of animal anthrax has likewise decreased so that only occasional cases are reported and epizootics have not been reported for a number of years. This reduction is the result of improved animal husbandry and the appropriate utilization of animal anthrax vaccine.

3. Methodology

3.1. Sources of Mortality and Morbidity Data

In the United States, data on human anthrax are collected in individual states through the routine surveillance system. Usually, individual case data are obtained by the use of special case-reporting forms and investigations. These data are then reported by means of the morbidity reporting system (National Notifiable Diseases Surveillance System—NNDDS) to the Centers for Disease Control and Prevention (CDC). Epidemic information and, at times, individual case data are reported to the CDC by telephone. Years ago, the reporting of anthrax was spotty; however, as health-care providers have accepted their responsibilities to notify public health officials about the occurrence of reportable disease, overall surveillance has improved. Additionally, as the incidence of the disease has decreased and the use of laboratory in assisting in diagnosing the disease has increased, reporting has become more complete.

Due to increasing concern about bioterrorism, potential bioterrorist agents have been classified according to their significance as agents. Category A agents are those with the greatest potential for causing the most significant morbidity and mortality and *B. anthracis* is in this category. The isolation and identification of any of these agents are to be reported immediately by telephone to CDC.

Data concerning anthrax in animals are obtained through federal and state departments of agriculture or public health or both.

Worldwide data on anthrax are available from the World Health Organization (WHO) and the Food and Agriculture Organization. However, not all countries maintain adequate surveillance programs for infectious diseases, and thus all do not have data available on cases of human or animal anthrax. Reports of anthrax associated with rural areas, i.e., animal-associated cases, will be especially deficient because of the generally poorer reporting of diseases from rural areas. Another source of data is ProMed, the worldwide computerized program for the reporting of the occurrences of infectious diseases in which a report of a case or an epidemic of anthrax may be published, even though it was not officially reported to the country's central health authority. Additionally, reports of epidemics in the scientific literature may give the actual number of cases of the disease that occurred, whereas the number if reported to the health authorities may only include those cases confirmed in the laboratory.

3.2. Surveys

Population surveys are not practical due to the low incidence of the disease. Serological surveys are not generally useful for obtaining information on anthrax, except in epidemic or epizootic investigations, because of limitations of the laboratory procedures. However, they may also be useful in ascertaining immunity levels in human and livestock populations.

3.3. Laboratory Diagnosis

3.3.1. Isolation and Identification Swabs from cutaneous lesions, vesicular fluid, or blood may be examined for

the presence of *B. anthracis*.[7] *Bacillus anthracis* is a gram-positive, nonmotile, hemolytic, spore-forming bacillus (1–1.3 ×.3–10 μm) that grows on ordinary laboratory media at 37ºC, producing round, grayish-white, convex colonies having comma-shaped outshootings with a ground-glass appearance that measure 2–5 mm in diameter. Colonies first appear approximately 8–12 h after inoculation of the agar and show the typical characteristics 24–36 h after inoculation. When an inoculated loop is drawn through the colony, tenacity is demonstrated; the disturbed part of the colony will be drawn perpendicular to the agar and will remain in this position, resembling beaten egg white. Microscopic examination (such as by Gram's stain) of growth from artificial media shows long parallel chains of organisms with square ends, described as "boxcars." Spore stains will reveal central or paracentral spores in *B. anthracis* organisms that have incubated at least 24 h. Material from a fresh lesion will show shorter chains with single or two to four organisms in a row with slightly rounded ends. Direct fluorescent-antibody staining specific to either the cell wall or the capsule may also be used to identify the organisms from vesicular fluid cultures or from tissues.[8] A newer method to identify *B. anthracis* in formalin-fixed tissue sections is immunohistochemical staining using monoclonal antibodies against *B. anthracis* cell wall and capsule.[9]

A bacteriophage designated gamma phage may be used to confirm the identification of *B. anthracis*.[10] Toxin production assays and DNA probes (PCR) for the presence of pX01 and pX02 plasmids are newer identification methods available in some reference laboratories.[11] The DNA probe can be sued to identify *B. anthracis* in nonviable specimens. Subcutaneous or intraperitoneal inoculation of guinea pigs, mice, or rabbits with agar-grown cells suspended in saline may be useful in differentiating *B. anthracis* from other gram-positive bacilli. *Bacillus anthracis* will cause death from 24 to 72 h after inoculation, and the animal will show evidence of general toxicity and multiple organ hemorrhages. Animals inoculated subcutaneously demonstrate subcutaneous gelatinous, hemorrhagic edema in addition to general toxemia. Broth-grown cultures must not be used because nonspecific death can result.

Tissue from autopsied patients should be cultured and microscopically examined.

3.3.2. Serological and Immunologic Diagnostic Methods. The virulence of *B. anthracis* is determined by the presence of three components: edema toxin, lethal toxin, and capsular material. To exert their effect within cells, both toxins require participation of a common transport protein called protective antigen. The capsule material contains poly-D-glutamic acid, which helps protect the bacillus from ingestion by phagocytes. Production of the toxic factors is regulated by one plasmid (pX01) and that of the capsular material by a second plasmid (pX02).

An enzyme-linked immunosorbent assay (ELISA) has been developed to measure antibodies to the lethal and edema factors and the protective antigen. A fourfold rise in titer or a single titer of greater than 1:32 is indicative of current or recent infection or acquired immunity.[12,13] An electrophoretic-immunotransblot test (western blot) that measures antibody to the protective antigen and the lethal factor is used to confirm ELISA results, or as the primary diagnostic test. Assays have been developed to detect the presence of the protective antigen component of the toxin in vesicular fluid as well as serum and cerebrospinal fluid (CSF).[12,14] There is a rapid card test that is used in veterinary medicine.[14]

3.3.3. Pathology. Autopsy material, commonly from the mediastinal structures, lymph nodes, spleen, and liver, should be examined for organisms and pathological changes.[15] The most significant findings at autopsy are those seen in patients who have died of inhalational anthrax. The classic finding is that of hemorrhagic mediastinitis with enlarged, hemorrhagic lymphadenitis. There may be inflammation of the pleura and some pleural effusion. Acute splenic may also be seen. Some patients may have hemorrhagic meningitis, and in one patient, hemorrhages were seen in the gastrointestinal tract.[16]

In deaths due to the abdominal form of gastrointestinal anthrax, there typically is hemorrhagic enteritis with congestion, thickening, and edema of the intestinal walls. Mucosal ulcers with necrosis may be seen in the stomach, terminal ileum, and cecum. The regional lymph nodes are enlarged, edematous, and hemorrhagic with some necrosis. There may be acute splenitis. Peritonitis with ascetic fluid is present.

In some patients with significant cutaneous lesions on the head and neck or the oropharyngeal form of gastrointestinal anthrax, marked anterior cervical subcutaneous edema may compress the trachea at the thoracic inlet. Death in such patients is due to asphyxiation.

4. Biological Characteristics of the Organism

The resistance of the spore form of *B. anthracis* to physical and chemical agents is reflected in the persistence of the organism in the inanimate environment. Organisms have been demonstrated to persist for years in buildings formerly used as factories in which the environment became contaminated during the processing of contaminated imported materials of animal origin. Accordingly, they may serve as the source of infection for people who work in the area. Special efforts are required to decontaminate this

environment; one method is to use paraformaldehyde vapor, which is successful in killing *B. anthracis* spores. However, due to concern about the potential carcinogenicity formaldehyde products, other disinfectants have been substituted such as chlorine dioxide and hydrogen peroxide vapor.[17] In the mail-associated bioterroristic event of 2001, the internal environment of post offices, commercial buildings, and commercial offices became contaminated with *B. anthracis*. Decontamination of large buildings is expensive, with the use of a protocol primarily dependent on aqueous chlorine at one mail handling facility costing $464,000. The cost of decontaminating the office building on Capitol Hill was approximately $28 million and the cost for decontaminating the two large mail centers was approximately $200 million.[17] In the laboratory, surfaces may be decontaminated with either 5% hypochlorite or 5% phenol (carbolic acid); instruments and other equipment may be autoclaved.

Bacillus anthracis may also persist in certain types of soil for years.[18] Alluvial soil with a pH greater than 6.0 is best suited for survival of *B. anthracis*. Persistence of the organism in soil plus environmental conditions such as climatic variations, i.e., flooding or drought, triggering brief periods of bacterial growth thought to be associated with outbreaks of anthrax in animal anthrax are known as anthrax districts. One such area is the lower Mississippi River valley area, from which sporadic outbreaks of animal anthrax have been reported at irregular intervals for years. The molecular structure of *B. anthracis* organisms can be typed and this has proven useful in defining the geographic distribution of specific strains.[19] The same technology has been used in forensic investigations.

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

In 1958, Glassman,[20] using reports from the WHO, estimated the annual worldwide incidence of human anthrax to be from 20,000 to 100,000 cases. Data from the WHO[21] for 1981 reported 3,200 cases from 43 countries, which undoubtedly is an underestimate. A review of reports from the WHO, Food and Agricultural Organization, and the Office Internationale des Epizooties for the 1900s provides some more recent data, but it is no more accurate than the previous estimates. In 1993, 1915 human cases were reported from 16 countries with 14 other countries reporting no cases, and in 1994, 694 cases were reported from 13 countries with another 17 countries reporting no cases. Animal anthrax remains an endemic problem in various Asiatic, African, South American, and Caribbean countries, as well as in Australia.[22] In countries with a significant animal anthrax problem, there is probably a related human anthrax problem. In China, for example, an average of 2,115 human cases were reported annually in the period 1989–1993, primarily related to butchering and consuming infected livestock.[22] However, since the reporting of diseases from rural areas is sporadic, these data are not generally available. Industrial anthrax infections are related to the processing of animal products such as goat hair, wool, skins and hides, and dried bones. Industrial countries that process these materials will have industrially related cases at a rate inversely proportional to the level of development of appropriate hygienic measures directed at reducing the threat of anthrax.

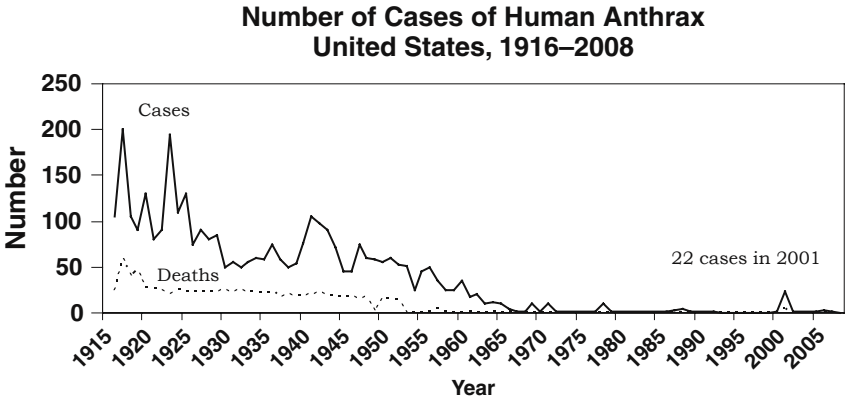

Figure 1. Anthrax in man in the United States, 1916–1996.
Source: NOVS and MMWR data.

In the United States, the annual number of cases of human anthrax decreased from an average of 127 for the years 1916–1925 to 44 cases for 1948–1957, to 9.6 cases for 1958–1967, to 2.4 cases for 1968–1977, to 0.9 case for 1978–1987, to 0.3 case for 1988–1996, to 0.45 cases (excluding the bioterrorist cases) or 2.55 cases (including the bioterrorist cases) for 1997–2007 (see Figure 1).

Approximately 95% of anthrax cases in the United States are cutaneous and 5% are inhalational; confirmed cases of gastrointestinal anthrax have not been reported in the United States but have been reported in other countries. Some investigators report that from 5 to 10% of cases worldwide may be gastrointestinal cases, i.e., one such case to every 100–200 cutaneous cases. From 1955 to 1996, 262 cases of anthrax were reported in the United States; 240 cases were cutaneous (21 of which were at unknown sites) and 22 were inhalational. Of the 203 cutaneous cases for which the sites of infection were reported, the majority occurred on the exposed part of the body, with 51% on the arms, 27% on the head and neck, 5% on the trunk, and 3% on the legs (see Table 1).

It is estimated that approximately 20% of untreated cases of cutaneous anthrax will result in death. Of the 224 cutaneous cases that have been reported in the United States since 1955, 11 have been fatal. Prior to 2001, inhalational anthrax was almost always fatal; between 1900 and 2000, 16 of the 18 cases reported in the United States were fatal.[23] However, in the bioterroristic event of 2001, six of the 11 inhalation cases survived due to rapid and aggressive treatment (see Section 8.1.2).[23]

In the few reports available, the mortality from gastrointestinal anthrax has usually ranged from 25 to 60%. In 1989, a gastrointestinal anthrax epidemic in Tibet resulted in 507 cases, including 162 deaths (32%).[24]

Table 1. Sites of 264 Anthrax Infections, United States, 1955–2007

Sites	Infections	Distribution	
		Number	Percent
Cutaneous	220		
Arms		131	50
Head and neck		69	26
Trunk		12	5
Legs		8	3
Unknown	21	21	8
Inhalation	23	23	9

5.2. Epidemic Behavior and Contagiousness

The first reports of inhalational anthrax (woolsorter's disease) in England in the late 1800s and early 1900s included clusters of cases associated with the sorting of certain lots of imported wool, frequently mohair.[25] In the United States, occasional epidemics occurred in industrial settings, epidemiologically related to the processing of batches of highly contaminated imported animal fibers, particularly goat hair. These epidemics were primarily of cutaneous anthrax.

The largest epidemic prior to 2001 reported in the United States occurred in 1957, and involved employees in a goat-hair-processing plant.[26] Among the 600 employees over a 10-week period, there were nine cases of anthrax: four cases of cutaneous anthrax and five of inhalational anthrax. None of the patients with cutaneous anthrax died, but four of the five with inhalational anthrax died. Epidemiological investigations related the cases to a particular contaminated batch of goat hair imported from Pakistan.[27] More than 50% of samples from this particular batch were culture positive for *B. anthracis*. A detailed examination of production records revealed that each of the patients could have had direct contact with this particular lot of goat hair during an appropriate period before the onset of disease.

An outbreak of human anthrax occurred in north central Russia (Sverdlovsk) in 1979, in which the source of infection was an accidental release of *B. anthracis* aerosol from a biological warfare research laboratory.[28] The exact number of cases is uncertain, but at least 77 persons developed inhalational anthrax subsequent to exposure in a narrow 4-km-long zone south of the laboratory. Deaths in sheep occurred up to 50 km from the laboratory as a result of the same accidental release. However, anthrax in sheep had been reported for years before the accident in Sverdlovsk, so whether these cases are related to the accidental release or not is not clear. This incident is the largest inhalational anthrax epidemic reported.

Over a 2-month period, September to early November, 2001, 22 cases of anthrax, 11 inhalational and 11 cutaneous, occurred in Florida, New York, New Jersey, Connecticut, and in Washington, DC. The source of infection was primary- and secondary-contaminated mail and the subsequent contamination of the environment of involved post offices and office buildings. Four recovered mailed letters contained powder and *B. anthracis* spores; there were more such letters, but they were not recovered. It is theorized, with good epidemiologic supporting evidence, that other letters being processed in post offices could have been secondarily contaminated with *B. anthracis* spores that then served as the source of infection for others.[29,30]

Human-to-human transmission of anthrax has rarely been reported. A recent report on anthrax in China included information on 10 cases of person-to-person transmission in a medical staff.[24] However, data are not presented that confirm these cases as representing human-to-human transmission. Industrial infections result from exposure to the organisms in the industrial environment, from contact with organisms either in the materials actually being processed, or in the environment that has been contaminated by previously processed materials. Those employees who work in the earliest processing stages, in which the materials and the environment are more heavily contaminated with *B. anthracis*, are at greater risk of contracting anthrax than those who work with the materials at later stages in the manufacturing cycle. Occasional cases occur in persons who have direct or indirect contact with *B. anthracis* in a laboratory setting.

Agricultural cases occur in veterinarians and others who have direct contact with animals that have died of anthrax. There have been cases of human disease associated with epizootics of anthrax in cattle. The largest reported agricultural outbreak occurred in Zimbabwe with more than 10,000 cases reported between 1979 and 1985.[31] The peak number of cases, more than 6,000, were reported to have occurred in the involved area. The majority of patients had cutaneous infections located primarily on the exposed part of the body; some gastrointestinal cases were reported. Domestic cattle deaths were also noted. The humans were infected from contact with the diseased animals or by handling their carcasses during butchering or burial; the source of infection for the animals was not reported. Routine animal vaccination had not been practiced.

5.3. Geographic Distribution

Cases are distributed according to their association with an agricultural or industrial source of infection. From 1920 to 1954, more than 50% of all cases in the United States occurred in Pennsylvania, New York, New Jersey, Massachusetts, and New Hampshire, the location of industries that processed animal hair, hide, and bone.[32] Subsequently, industrial cases began to be reported from other states, such as North Carolina and South Carolina, as companies moved southward. In more recent years, cases have not shown a geographic localization, reflecting the decrease in industry-related cases and the low endemicity of agriculture-related cases.

Agriculture cases are distributed in rural areas associated with outbreaks in animals and primarily occur in the previously discussed anthrax districts. Some of these districts are located in Louisiana, Mississippi, and South Dakota.[18] Domestic epizootics commonly involve cattle, but sheep, swine, and horses are also susceptible. Cases have also been reported involving white tailed deer and moose. In Canada, cases have been reported in buffalo. Cases and epizootics have also been reported in domestic and wild animals in Asia, Africa, Europe, especially eastern Europe, and Australia. The source of infection for wild animals in captivity is infected foods; for domestic range cattle or wild animals not in captivity, the source is contaminated soil. Biting flies have been reported as transmitters of infections.[33]

5.4. Temporal Distribution

Industrial cases occur throughout the year without any seasonal pattern. Animal-related cases occur primarily in the spring and summer, the seasons when animal anthrax cases occur with the greatest frequency.

5.5. Age

The age distribution of cases reflects the age of individuals who work in the involved industry or come in contact with infected carcasses. Primarily, these persons are 20–60 years of age. Occasional cases have been reported in children, one of whose parents worked in a factory in which *B. anthracis*-contaminated materials were processed; it has been hypothesized that *B. anthracis* organisms were transported into the home on the parent's clothing. In Haiti, the distribution of cutaneous anthrax cases by age group was reported as being generally comparable to that of the general population, with the anatomic distribution of lesions being similar in all age groups.[34]

5.6. Sex

The predominance of males reflects the sex distribution of the people who work in the involved industries or have contact with infected carcasses.

5.7. Race

No distinctive racial patterns are found among persons with anthrax.

5.8. Occupation

Anthrax cases may be divided into two major categories: those associated with an industrial setting and those associated with an agricultural setting (see Table 2). However, some cases occur in people who live in urban areas in which the source of infection is unknown; in these cases, the source is assumed to be industrial. In addition, a few laboratory-associated cases have been reported.

Table 2. Source of Infection in 264 Cases of Human Anthrax, United States, 1955–2007

Source	Number
Industrial	
Goat hair	113

Goat skins	19
Meat	3
Bone	4
Unknown	12
Agricultural	
Animal	46
Vaccine (animal)	2
Unknown	8
Bioterrorism	
Direct	22
Indirect (laboratory)	1

Industrial cases have occurred in individuals who worked in industries in which animal products, usually imported, were processed.[32,35] In the United States, this primarily involved workers in goat-hair- and wool-processing industries. Goat hair was imported primarily from Asiatic, Middle Eastern, and African countries in bales weighing 200–250 lb each. The hair was processed into yarn used in preparing interlinings for men's suit coats and also into a felt material used as underpads for carpets, insulation for pipes, saddle pads, and washers. The wools that have been implicated in cases of anthrax are imported from the same areas of the world and are primarily the coarser wools used in carpets as distinct from the finer wools used in clothing. Occasionally, however, anthrax has been associated with fine cashmere wool.

Anthrax has also been associated with the tanning industry and has resulted from contact with imported skins and hides. Cases have also been associated with the bone-meal-processing industry, in which dried bones are imported for preparing bone meal for fertilizer, animal food supplements, or gelatin. The dried bones are usually gathered from animal grazing areas and animals that have died of unknown causes. However, bones may also be obtained from slaughtering or rendering plants.

There have been cases in which the source of infection has been domestic animal products. For example, in 1924, a number of persons developed cutaneous anthrax following their contact with hides from animals that died during an epizootic of anthrax.

Occasional cases have been reported among persons who have had contact with horsehair and pig bristles that are used in brushes, such as shaving brushes or hair brushes. The number of cases associated with contaminated imported shaving brushes was significantly reduced in the 1920s by the enactment of laws requiring that these brushes be shown by culture to be free of B. anthrax organisms when imported into the country. In recent years, the use of animal fibers has decreased as synthetic materials have been used in increasing quantities. Accordingly, this risk of anthrax is negligible. Among the 22 cases of anthrax associated with bioterrorists event of 2001, 12 were mail handlers, nine occurred in persons who were United States Postal Service employees.[29]

Agricultural cases have also occurred in individuals who used fertilizer or animal feed that contained contaminated bone meal. One particular epidemic related to feed supplement for pigs involved 846 cases in pigs, with some cases in persons who had contact with the pigs.[36]

Occasional cases have occurred in individuals who have had no known contact with industrial or agricultural sources. Usually, their cases are thought to have been caused by environmental contamination such as in the case of a housewife who lived near a tanner and died of inhalational anthrax. Another case occurred in an individual who every day walked by the receiving room door of a tannery where contaminated hides were processed.[37] It was shown that air could have flowed from the receiving area out into the street, where the individual could have inhaled an infecting dose of airborne *B. anthracis* organisms. At least 77 cases of inhalational anthrax occurred in Sverdlovsk, Russia in 1979, associated with the accidental release of an aerosol from a biological warfare research laboratory.[28]

Several cases have occurred in persons whose contact has been in laboratories in which strains of *B. anthracis* have been handled.[38] Two of these cases were fatal inhalational cases.

5.9. Cases Related to Commercial Products

An occasional case has occurred in an individual after contact with a commercial product prepared from animal materials. Examples of cutaneous anthrax include contact with imported souvenir drums with drumheads made of goatskin[39] and a case in which the source of infection was most likely a newly purchased woolen coat. A fatal case of inhalational anthrax occurred in a home weaver following contact with imported yarn that contained animal fibers.[40] Three cases of anthrax in the United States, one inhalational, occurred in individuals who worked with imported animal skins that were being processed into drum heads.[41,42]

5.10. Socioeconomic and Other Factors

Socioeconomic or other factors may contribute significantly to the risk of an anthrax infection. Among some people in certain societies, economic problems lead to individuals salvaging the meat, hair, or hides from carcasses of

animals that died from gastrointestinal anthrax and related to butchering and consuming raw or undercooked meat from anthrax-infected carcasses, they developed anthrax.

6. Mechanisms and Routes of Transmission

In the United States, *B. anthracis* organisms are primarily transported by the contact or the airborne routes. Organisms can also be transmitted by a common vehicle, food (meat), though this is rare. Vectors (flies) have been reported to transmit organisms, although the actual relationship to subsequent disease has not been proven. In Asian and African countries, the gastrointestinal route is more common.

Contact spread is primarily by indirect contact, although direct contact and droplets may also be routes of transmission, and results in cutaneous lesions, most frequently on the exposed parts of the body. Direct contact spread occurs when a susceptible host has direct contact with an animal that is infected with *B. anthracis*, such as a veterinarian who autopsies an animal contaminated with the organism. Organisms may enter the body through a preexisting skin wound or may be accidentally injected by a sharp bone spicule or a knife.

Meat from an animal that died from anthrax is usually infected and can serve as a source of infection if eaten undercooked. Persons preparing the meat for consumption are at risk of cutaneous anthrax.

Indirect contact spread accounts for the majority of cutaneous industrial cases. The source of infection is either the animal products being processed or the environment that has been contaminated by animal products previously processed. Rarely, the finished product may be the source. By this route, organisms enter the skin through a preexisting wound, a new wound, or the mucous membranes (i.e., conjunctivae). Goat hair fibers may be flung from the manufacturing equipment like projectiles and enter the skin like needles, depositing *B. anthracis* organisms in the subcutaneous tissues.

Aerosols containing *B. anthracis* spores may be created by agitation of the hair or wool either when the bales are being opened or the fibers initially handled or as the fibers are being processed through the machinery. These aerosols may travel more than several feet, which represents airborne transmission. Particles less than 5 μm in diameter, if inhaled, may reach the terminal alveoli of the lungs and cause inhalational anthrax (see Section 7.1.2). The estimated human LD_{50} dose from inhaled small-particle aerosols has been estimated to be 8,000–10,000 spores.[43] The minimum infecting dose for humans is unknown. Essentially all the risk of infection occurs during exposure to the primary aerosol generated during processing. Inefficiency of small-particle aerosol deposition and resuspension minimizes any potential risk of significant secondary aerosol.[28]

The air in several goat-hair-processing plants has been sampled, and significant levels of airborne *B. anthracis* spores have been identified. For example, studies in a goat-hair-processing plant in the Northeast in 1958 demonstrated that "510 spores in particles 5 microns and less in size may be inhaled [by workers] in 8 hours without inducing infection."[43] In a similar mill in a southern state, 91 primates (cynomolgus monkeys) were exposed during a series of experiments to the air in the dustiest part of the mill.[44] They had an anthrax mortality rate of 10–25% from a calculated inhalation dose of 1,000–5,000 *B. anthracis* organisms accumulated over 3–5 days.

Animals become infected by ingestion of contaminated soil or feed. Some rural areas are associated with sporadic cases or outbreaks of animal anthrax. The soils in these areas are most frequently in the neutral pH range and are alluvial or loessal soils. Soil becomes contaminated from the discharges or carcasses of dead animals. Soil can also become contaminated from use of contaminated fertilizer or feed. It is reported that the spores may remain infectious in nature for many years, though this has never been scientifically proven. There is evidence to suggest that in some areas *B. anthracis* organisms can be considered as part of the endogenous soil flora. With certain climatic conditions, the spores germinate and multiply, resulting in an increase in the number of infectious organisms that could be ingested by susceptible grazing animals.

Insect vectors, such as horseflies, have been reported to transmit *B. anthracis* by means of mechanical transfer of *B. anthracis* organisms from contaminated foci to individuals or animals.[33] Outbreaks of animal anthrax have been reported to result from transmission of *B. anthracis* by horseflies from an infected animal to a second animal. However, there is no scientific documentation, including field studies during an epizootic, that this potential method of transmission has any practical significance.

7. Pathogenesis and Immunity

7.1. Pathogenesis

7.1.1. Cutaneous Anthrax. The incubation period is from 3 to 10 days, most commonly 5–7 days. However, there have been some reports of lesions developing as soon as 9 h after the reported exposure.[45] Spores deposited beneath the skin germinate, and the resulting vegetative forms multiply and produce a toxin. The local lesion results from the action of the toxin on the surrounding tissue, which causes tissue

necrosis. This leads to the development of a scar at the site of the lesion. The toxin or organisms or both may be distributed throughout the body by the vascular system, causing systemic symptoms and signs of toxicity or bacteremia. Occasionally, organisms are picked up by the lymphatic system, resulting in lymphangitis and lymphadenopathy.

7.1.2. Inhalational Anthrax. The incubation period is usually stated to be 1–5 days (mean 3–4 days). However, in the epidemic of inhalational anthrax in Sverdlovsk, the incubation periods ranged from 4 to about 45 days (median 9–10 days).[28] The explanation for the prolonged incubation period is unknown, but may represent low-dose phenomenon or prophylactic use of antibiotics. *Bacillus anthracis*-bearing particles less than 5 μm in size are inhaled and, if they reach the terminal alveoli, are deposited on the alveolar membranes, where they can be ingested by alveolar macrophages, carried across the membranes to the regional lymph nodes, and deposited. Spores will then germinate, multiply, and produce toxin. The toxin, in turn, destroys tissue and subsequently causes necrosis and hemorrhage. The classic picture at death is very distinctive. Examination of the mediastinal area reveals hemorrhagic mediastinitis with varied degrees of destruction of the normal architecture.[46,47] While the pathological changes are limited to the mediastinal area, there may be secondary involvement of the pulmonary tissue. Toxin may be distributed throughout the body, resulting in systemic symptoms and signs. Organisms may also be picked up by the vascular system, resulting in bacteremia and septicemia. The pathogenesis and radiological findings of inhalational anthrax can be found at http://anthrax.radpath.org.

7.1.3. Gastrointestinal Anthrax. The incubation period is commonly 3–7 days. There are two clinical presentations following ingestion of *B. anthracis*-contaminated food: abdominal and oropharyngeal.

In the abdominal form, spores are ingested, absorbed through the intestinal mucosa, probably via M cells in the epithelium overlying Peyer's patches, and deposited in mucosal lymphoid tissue or regional lymph nodes; here, they germinate, and the vegetative cells multiply, producing toxin. An ulcerative lesion caused by the action of the toxin may develop within the mucosa of the gastrointestinal tract. The lesions are frequently described in the cecum and adjacent areas of the bowel. Some reports have described lesions in the large bowel, stomach, and rarely in the duodenum.[48] Alternatively, lymphadenitis or lymphadenopathy may occur. Hemorrhagic areas may develop within the mesentery as well as in the gastrointestinal tract.

In the oropharyngeal form, organisms are transported through the oral mucosa to the tonsils or cervical lymph nodes, where they germinate, multiply, and produce toxin. The result may be edema and tissue necrosis in the cervical area. There is a report from Thailand as well as several other countries of the development of an inflammatory lesion resembling a cutaneous lesion in the oral cavity involving the posterior wall, the hard palate, tongue, or the tonsils.[49]

7.2. Immunity

Apparently, once having had a cutaneous lesion, an individual develops some degree of immunity against another infection. There have been no well-confirmed second cases of cutaneous anthrax in individuals who have had a confirmed first case. There have been several reports of two cutaneous anthrax infections in the same individual; however, in each of these reports, either one or both of the cases of anthrax have not been well documented.[45]

Extensive serological studies have not been conducted. In one study, however, Norman et al.[50] studied 72 unvaccinated employees in a goat-hair-processing mill, none of whom had a history of an anthrax infection. Of the 72, 11 demonstrated a positive titer (precipitation-inhibition test), suggesting previous subclinical infection. Recovering cutaneous and gastrointestinal anthrax patients develop antibody to the toxin components as determined by ELISA and electrophoretic-immunotransblot (Western Blot) testing.[51]Antibody and cell-mediated immunity studies of persons exposed during a terrorist attack on the United Senate Office Building suggested possible subclinical infection in exposed persons who had received antibiotic prophylaxis but did not develop symptoms.[52]

Detailed data concerning immunity following inhalational anthrax are not available because of the rarity of this form of the disease and the high fatality rate. In studies of the several persons who have recovered during the past 25 years, low levels of antibodies were detected following recovery from the clinical disease.

8. Patterns of Host Responses

8.1. Clinical Features

8.1.1. Cutaneous Anthrax. Typically, cutaneous anthrax occurs on the exposed parts of the body. Although a single cutaneous lesion is typical, some patients develop multiple discrete lesions. The lesion begins innocuously with a small papule that the patient may first notice because of pruritus. The papule develops after several days into a small vesicle or, occasionally, into several vesicles that then coalesce to form a ring. This area may be surrounded by a small ring of erythema and possibly some edema. The pruritus may continue, but there is no pain unless

secondary infection or a significant degree of local edema is present. A small dark area can be seen beneath the center of the vesicle or in the central area if a ring of vesicles has formed. Eventually, the vesicle or vesicular ring ruptures, discharging a clear fluid and revealing a depressed black necrotic central area known as an eschar. After 1–2 weeks, the lesion dries and the eschar begins to loosen and shortly thereafter separates, revealing a permanent scar.

The lesion is usually 1–3 cm in diameter and remains round and regular. Occasionally, a lesion may be larger and irregularly shaped. There may be regional lymphangitis and lymphadenopathy and some systemic symptoms such as a slight low-grade fever, malaise, and headache. Antibiotic therapy will not change the natural progression of the lesion itself; however, it may decrease or inhibit development of edema and systemic symptoms. Clinical progression may lag behind bacteriological cure by 24–48 h.[53]

Occasionally, the cutaneous reaction is severe and is characterized by significant local and spreading edema associated with blebs, bullae, induration, chills, and fever. This type of reaction is referred to as malignant edema. Whether malignant edema results from increased pathogenicity or dosage of the organism or because of host factors is unknown.

There have been reports of multiple simultaneous lesions on a patient, but laboratory confirmation of each lesion has been lacking.[53]

Lesions in specific body sites occasionally result in more severe local reactions. Several cases have been seen of anthrax involving tissue surrounding the eye in which extensive edema spread over the entire face and extended to the neck and upper thorax. In one such patient, edema involved his entire face and extended down to the upper part of the thorax. In this instance, the spread of the toxin resulted in an extensive cutaneous lesion with necrosis of both eyelids. Plastic surgery was necessary to repair the tissue damage of the eyelids and surrounding tissue. Plastic surgery may also be necessary for other significant lesions.

Infrequently, meningitis may develop as a complication of cutaneous anthrax (see Section 8.1.4).

8.1.2. Inhalational Anthrax. This form shows a biphasic clinical pattern with a benign initial phase followed by an acute, severe second phase.[26,54] The initial phase begins as a nonspecific illness consisting of malaise, fatigue, myalgia, mild fever, nonproductive cough, and, occasionally, a sensation of precordial oppression. Findings of the physical examination are essentially within normal limits except that rhonchi may be present. The illness may resemble a mild upper-respiratory-tract infection such as a cold or the "flu." After 2–4 days, the patient may show signs of improvement. However, there is then the sudden onset of severe respiratory distress with dyspnea, cyanosis, respiratory stridor, and profuse diaphoresis. In several cases, subcutaneous edema of the chest and neck has been described. The pulse, respiratory rate, and temperature become elevated. Physical examination reveals moist, crepitant rales over the lungs and possibly evidence of pleural effusion. Shock may develop. X-ray examination of the chest may reveal widening of the mediastinum and/or pleural effusion. Septicemia and meningitis may develop. Without rapid treatment with antibiotics respiratory support, and attention to the electrolytes, death occurs within 24 h after the onset of the acute phase. Among the 16 survivors of the bioterrorist attacks, including six who recovered from inhalational anthrax, nine who recovered from a cutaneous lesion were studied approximately 1 year after their illness. They continued to report significant health problems and poor life adjustment that impacted on their quality of life.[55] A review of 82 inhalational anthrax cases from 1900 to 2005 summarizes the clinical data available from the patients' records.[23] There is a report of an inhalational anthrax-like illness due to infection with *Bacillus cereus* strains carrying the pX01 and pX02 plasmids.[56]

8.1.3. Gastrointestinal Anthrax. There are two clinical presentations for disease resulting from ingestion of *B. anthracis*: abdominal and oropharyngeal.[57,58] The symptoms of abdominal anthrax are initially nonspecific and include nausea, vomiting, anorexia, and fever. With progression of the disease, abdominal pain, hematemesis, and bloody diarrhea develop. Ascites may be present. Occasionally, the symptoms and signs resemble an acute surgical abdomen, which in some cases has resulted in surgery. With further progression, toxemia develops with shock, cyanosis, and death. The time from onset of symptoms to death has most frequently varied from 2 to 5 days. In oropharyngeal anthrax (also referred to as cervical anthrax), patients have experienced fever, submandibular edema, cervical lymphadenopathy, and anorexia. Some reports describe the presence of acute inflammatory lesions in the oral cavity and/or oropharynx. The mortality rate for gastrointestinal anthrax has been reported to vary from 25 to 60%.

8.1.4. Other Forms. Meningitis, seen in less than 5% of anthrax cases, may be a complication of any of the three forms of primary anthrax infection. In the bioterrorist attack, meningitis was seen in half of the inhalational cases. Rarely, meningitis is reported without a known primary site of infection. Symptoms of meningeal anthrax develop one to several days after the onset of the primary lesion and are similar to those associated with hemorrhagic meningitis. Death, if it occurs, usually does so in 1–6 days after onset of disease. Septicemia is only rarely seen in patients with treated cutaneous lesions; it is more commonly seen in patients with inhalational and gastrointestinal anthrax.

8.2. Diagnosis

A source of exposure to the infectious agent is of importance in considering a diagnosis of anthrax. Only rarely have cases occurred for which the source of infection could not be identified.

Cutaneous anthrax should be suspected when an individual describes a painless, pruritic papule, usually on an exposed part of the body. Vesicular fluid should reveal *B. anthracis* organisms microscopically and on culture. The differential diagnosis should include contagious pustular dermatitis (ecthyma contagiosum or orf), milker's nodule, plague, staphylococcal disease, and tularemia.

The initial symptoms of inhalational anthrax are nonspecific and may resemble those of an upper-respiratory-tract infection. Characteristically, with the sudden development of the acute phase, there is severe respiratory distress and radiographic examination of the chest should reveal widening of the mediastinum, a typical occurrence with inhalational anthrax (see http://anthrax.radpath.org). The acute phase resembles diseases that result in respiratory failure and shock.

In gastrointestinal anthrax, the patient presents with signs and symptoms of gastroenteritis. Organisms may be demonstrable in vomitus and feces from the infected individual. The differential diagnosis includes diseases that cause moderately severe gastroenteritis, such as shigellosis and *Yersinia* gastroenteritis. In the cervical form, the signs and symptoms might suggest pharyngitis, such as seen with streptococcal infections.

In anthrax meningitis, in most cases, there is a primary site of infection. CSF should contain *B. anthracis*. In septicemia, blood cultures should be positive for *B. anthracis*.

Several rapid diagnostic tests have been developed for specific diagnosis during the acute-phase illness. Toxin can be detected in clinical specimens using a capture ELISA or a chromatographic assay. Suitable specimens for toxin assay are vesicular fluid or lesion exudate in cutaneous cases, serum in gastrointestinal and inhalation cases, and CSF in meningitis cases.[14,59] Polymerase chain reaction detection of *B. anthracis*, whether living or dead, is possible utilizing primers targeting pX01 and pX02 plasmid DNA sequences.[11] Fluorescent-antibody staining of clinical and autopsy specimens is an older approach that has been updated through the use of monoclonal antibodies against cell wall and capsule components unique to *B. anthracis*.[8,14]

Serological tests currently being used in the United States include ELISA and electrophoretic immunotransblot (EITB).[51] Both tests are based on detecting components of the anthrax toxin. The ELISA test is used primarily for screening and is less specific than the EITB. The EITB can be modified to demonstrate titer changes between acute and convalescent serum samples.[9]

9. Control and Prevention

9.1. General Concepts

The risk of industrial infection has been reduced significantly over the past years as the use of imported animal products has been reduced because of changing business conditions, the increased use of synthetic materials, and the use of human vaccine (see Section 9.3). If imported materials for industrial use again become a problem, then disinfecting the animal products either before they are imported or when they enter the United States is important. Washing with formaldehyde, as was done at the Liverpool Disinfection Station in England for many years, could be used; other methods that could be instituted are ethylene oxide treatment, irradiation, or autoclaving. However, because imported animal products may enter the United States through a number of ports, and due to complexities of these decontamination procedures, development of a central facility in which to process the imported materials would be very difficult.

In the United States, improvements in industrial hygiene have been of some benefit in reducing the exposure of the worker to infectious materials and aerosols. The most important are the use of dust-collecting equipment during the initial processing cycle and institution of effective environmental cleanup procedures.

Employees should be educated about the disease and the recommendations for working in a contaminated environment and for reducing the risk of developing the disease. All employees should be vaccinated. Medical consultation services should be available to the employees. Adequate cleanup facilities and clothes-changing areas should be available so that workers do not wear their contaminated clothes home.

Gastrointestinal anthrax can be prevented by forbidding the sale of meat for consumption from sick animals or animals that have died from disease. Depending on the circumstances, it may be important to alert individuals who may come in contact with contaminated meat about the disease and about the need to cook all meats thoroughly.

All cases or suspected cases of anthrax should be reported to local public health officials so that appropriate epidemiological investigations can be conducted. Additional cases in humans or animals may be prevented by the prompt reporting and investigation of circumstances surrounding every case.

In the United States, agricultural anthrax is not a significant problem. This reflects the high standards of animal husbandry practiced in this country. Animals that graze in areas known as anthrax districts should be vaccinated annually with the Sterne strain animal vaccine. All animals suspected of dying from anthrax should be examined microbiologically; blood or tissue smears can be examined microscopically, and cultures can be set up from these same materials. All animals that have died with a confirmed diagnosis of anthrax should be thoroughly burned and the remaining bones and other materials buried deeply. Animals that die with a suspected diagnosis of anthrax can be cultured using a sample of blood. The carcass should then be handled as outlined above. If incineration is not possible, then the carcass should be covered with lime and buried at least 6-ft deep to discourage it being uncovered by scavenging animals.

9.2. Antibiotic Prophylaxis and Chemotherapeutics

Prophylactic antibiotics or chemotherapeutic agents are not used for anthrax except in three situations. If an individual has been inoculated with a live Pasteur-type spore animal anthrax vaccine, prophylactic penicillin should be given. Additionally, prophylactic antibiotics should be considered if a person is known to have eaten contaminated meat. The third situation is when an individual has been exposed to a high dose of *B. anthracis*. In these instances, post-exposure prophylaxis (PEP) is given to kill any *B. anthracis* organisms that may have been inoculated, ingested, or inhaled, and thus prevent the production of toxin. Persons with gastrointestinal or aerosol exposure should receive a 60-day course of antibiotics and be concurrently immunized with the human anthrax vaccine.[60] Laboratory studies with primates have evaluated the effectiveness of post-exposure prophylaxis and vaccination for inhalational anthrax. Protection was demonstrated using penicillin, ciprofloxacin, or doxycycline, and for doxycycline and vaccination.[61] When prophylactic antibiotics are given, the patient should be kept under surveillance for 10 days after initial therapy.

9.3. Immunization

There is an effective anthrax vaccine that was field tested in employees of four different textile mills in the United States, which demonstrated an effectiveness of preventing cutaneous anthrax of 92.5%.[62,63] The vaccine is a precipitate from a cell-free culture filtrate and contains protective antigen. This vaccine should be used for all employees who may be exposed to contaminated materials or environment. Additionally, anyone who comes into a mill-processing *B. anthracis*-contaminated material should also be vaccinated. Currently, the vaccine is given subcutaneously with three doses given at 2-week intervals followed by three booster inoculations at 6-month intervals and then annual booster inoculations. Alternate immunization schedules and routes of administration have been evaluated, and changes in the current recommendations may be adopted. Serological testing of vaccines has found a significant serological response to protective antigen beginning about 7 days after receipt of the second dose. Veterinarians, laboratory personnel, and other persons who, because of their occupation, have ongoing risk for contact with anthrax should also be immunized with the human anthrax vaccine. The human anthrax vaccine, BioThrax® is available on a limited basis. Those interested should contact Emergent Biosolutions, 2273 Research Boulevard, Suite 400, Rockville, Maryland 20850. Several new human vaccines are under development.

9.4. Immune Serum

In the 1800s and into the 1900s, hyperimmune serum was produced in horses and used to treat patients with cutaneous anthrax with some successes as reported in the literature. The hyperimmune serum was produced in Italy. Currently, anthrax globulin from anthrax vaccinees is available for inhalation anthrax therapy trials under an Investigational New Drug application with the Food and Drug Administration.

10. Unresolved Problems

The ecology of *B. anthracis* is poorly understood. Some investigators hold that *B. anthracis* is an obligate mammalian pathogen which persists in contaminated soil due to a highly resistant spore, but others postulate that *B. anthracis* has a growth phase in soil which compounds the risk posed by spore persistence. The latter hypothesis holds that the anthrax bacillus may utilize soil as a growth medium or perhaps replicate within components of the soil fauna such as nematodes or free-living amebae. The timing of animal anthrax outbreaks is difficult to explain solely on the basis of soil persistence, but efforts to grow the agent in soil have not produced convincing results. Certain soil factors such as pH and calcium content appear to be associated with soil districts that remain infectious for livestock for many years, but whether these factors support growth or simple spore persistence is unresolved. A better understanding of anthrax ecology is a key to more effective intervention.

Wildlife anthrax continues to be a problem, particularly in developing countries. Improved control measures are needed to preserve the affected species, minimize associated public health risks, and reduce potential environmental

contamination. Due to poor understanding of the risk factors contributing to wildlife anthrax, epidemiologic investigations are urgently needed to develop science-based control programs.

The major anthrax virulence factors have been well characterized in recent years. Less well studied are potential lesser virulence factors such as enterotoxin, and their role in anthrax pathogenesis.

The protective antigen-based vaccine that is currently approved for administration to humans in the United States provides good protection but requires multiple doses and does not result in rapid development of immunity. A recombinant protective antigen-based vaccine is being developed and evaluated, but this vaccine has similar problems. Vaccine development remains a priority. Also, the role of antiserum for post-exposure prophylaxis and case treatment needs more extensive evaluation. Early animal studies suggest that antiserum has a potential role if administered early in the course of the disease.

Post-exposure prophylaxis (PEP) clearly has a role in anthrax prevention, particularly in terrorist attacks. However, optimal practices remain to be defined. Which antimicrobial agents should be used? What is the optimal duration for PEP? What regimen should be followed in situations where post-exposure vaccination is also feasible? How should a general PEP recommendation be modified for special populations such as in persons with immunodeficiency and the aged? Can the same PEP recommendations be used for persons with cutaneous, intestinal, and inhalational exposure?

The extent, if any, of potential long-term sequelae of anthrax infection needs better definition. In cutaneous anthrax, surgical correction of problems arising due to scarring is occasionally necessary. However, limited information is available on other potential long-term effects of inhalational or gastrointestinal anthrax. A 1-year follow-up of anthrax survivors of the 2001 bioterrorist attacks revealed continuing psychological distress and reduced health-related quality-of-life indices, pointing to the need for further study.

CHAPTER 6

Bacterial Foodborne Disease

Heather Green, Jon Furuno, Amy Horneman, and J. Glenn Morris, Jr.

1. Introduction

Foodborne disease comprises a broad group of illnesses caused by the consumption of foods contaminated with toxic substances or pathogenic microorganisms. The agents responsible for foodborne illnesses can be divided into four general categories: chemical (e.g., mushroom or scombroid poisoning), parasitic (e.g., *Trichinella* or *Giardia*), viral (e.g., Hepatitis A or Norovirus), and bacterial (e.g., *Salmonella* or *Campylobacter*). Only the bacterial will be considered in this chapter.

Because there are many foodborne bacterial pathogens, it is useful to categorize them further. Epidemiologically, one of the most useful methods is to divide these according to their reservoir (Table 1). *Campylobacter*, Shiga toxin-producing *Escherichia coli* (STEC) (the most common of which is *E. coli* O157:H7; also known as enterohemorrhagic *E. coli*, or EHEC), nontyphoidal *Salmonella*, and *Yersinia* often live as commensals in the intestinal tracts of animals. They are transmitted to humans largely through beef (STEC and *Salmonella*), pork (*Yersinia*), poultry (*Salmonella* and *Campylobacter*), and eggs (*Salmonella* serotype Enteritidis). *Brucella* differs from the others in this group in that it usually acts as a pathogen in animals; it is transmitted from the animal reservoir to humans via the consumption of milk as well as via other routes. *Vibrio, Aeromonas*, and *Plesiomonas* species all inhabit aquatic environments and are transferred to humans through seafood (*V. parahaemolyticus, Aeromonas*, and *Plesiomonas*) or through water (*V. cholerae*, *Aeromonas*, and *Plesiomonas*).[1] Enterotoxigenic *E. coli* (ETEC), *Shigella*, *Salmonella typhi*, and *Staphylococcus* are species that are transmitted primarily from infected handlers through food. Finally, there is a group of organisms, including *Listeria, Clostridium perfringens, Clostridium botulinum*, and *Bacillus cereus*, that generally originate in environmental sources.

Alternatively, organisms can be classified according to the three main ways by which they produce illness: toxin production prior to consumption, toxin production in vivo, and invasion of the host (Table 2). Differentiation into the last two categories has become complicated in light of discoveries of genes for type III and type IV secretion systems in a variety of bacteria. These secretion systems inject bacterial virulence factors directly into host cells, allowing for activation of several biological functions that can eventually result in cell invasion. Despite this evidence, general assumptions about the predominant mechanism of bacterial pathogenesis can be made based on incubation period. Organisms in the first category, *C. botulinum, B. cereus* (emetic-type illness), and *Staphylococcus*, produce toxins as they grow in food. Because these toxins are completely formed by the time the food is consumed, vomiting or diarrhea due to the latter two have a short incubation period (1–6 h). As one might predict, the toxins produced by these organisms are generally resistant to stomach acid and to proteases found in the gastrointestinal tract. Organisms in the second category, *B. cereus* (diarrheal type illness), *C. perfringens*, and "toxigenic" *V. cholerae*, have an incubation period of 6 h to several days after ingestion and during this time are thought to elaborate toxins as they multiply within the gastrointestinal tract. The last category includes organisms that have either demonstrated adherence and invasion of cultured cells or have been discovered with type III or type IV secretion systems: *Aeromonas, STEC*, enteropathogenic *E. coli* (*EPEC*), *Brucella, Campylobacter, Listeria*, nontyphoidal *Salmonella,*

Table 1. Foodborne Pathogens, Classified by Reservoir

Animal reservoir (vehicles include meat, poultry, and eggs)	*Brucella*
	Nontyphoidal *Salmonella*
	Campylobacter
	Yersinia
	EHEC
Marine organisms (vehicles include seafood and water)	*Vibrio* species
	Aeromonas
	Plesiomonas
Human reservoir (transmitted through food contaminated by infected or colonized food handlers)	ETEC
	Staphylococcus
	Salmonella typhi
	Shigella
Other environmental (can be found in soil, water, or a variety of foods)	*C. botulinum*
	C. perfringens
	B. cereus
	Listeria

Salmonella typhi, Shigella, V. vulnificus, *V. parahaemolyticus*, and *Yersinia*. The incubation period for these organisms can be even longer, lasting from a few hours to several weeks. As stated earlier, these categories are not mutually exclusive. The pathogenesis of many foodborne pathogens is still incompletely understood, and many of the invasive organisms also elaborate toxins that may be important in their ability to cause disease.

Most of the bacteria that cause foodborne illness are discussed in separate chapters in this book (see Chapters 6, 7, 8, 11, 14, 21, 31, 32, 42, and 43). Because illness due to six organisms, *S. aureus, B. cereus, C. perfringens*, noncholera vibrios, *Aeromonas*, and *Plesiomonas*, is not discussed explicitly elsewhere, this chapter is devoted to these pathogens.

Table 2. Classification of Bacterial Foodborne Pathogens According to Pathogenesis

Organisms that cause disease by production of toxins in food prior to consumption	*B. cereus* (emetic type)
	C. botulinum
	Staphylococcus
Organisms that produce disease by production of toxins after ingestion	*B. cereus* (diarrheal type)
	C. perfringens
	Plesiomonas
	V. cholerae
Organisms that produce disease by invasion of the host	*Aeromonas*
	Brucella
	Campylobacter
	EHEC
	EPEC
	Listeria
	Nontyphoidal *Salmonella*
	Salmonella typhi
	Shigella
	V. paraheaemolyticus
	V. vulnificus
	Yersinia

2. Historical Background

In the United States formal surveillance for diarrheal illness began after World War I when state and territorial health officers, concerned about high morbidity and mortality rates caused by typhoid fever and infantile diarrhea, recommended that cases of enteric fever be investigated and reported. In 1923, the United States Public Health Service published summaries of outbreaks of gastrointestinal illness attributed to milk. Outbreaks caused by all foods were added in 1938. These activities were instrumental in the enactment of public health measures that have decreased the incidence of enteric disease.

In 1961, the Communicable Disease Center [which later became the Centers for Disease Control and Prevention (CDC)] assumed responsibility for collecting and publishing reports on foodborne illness. The current system of surveillance of foodborne disease outbreaks began in 1966, by incorporating into an annual summary all reports of such outbreaks in the United States.

The National Notifiable Diseases Surveillance System has been collecting data on sporadic illness (i.e., illness not associated with an outbreak) since 1912. In that year the Public Health Service began recommending immediate telegraphic reporting of five infectious diseases and monthly reporting of ten others. Since then, the systems have expanded to include 59 infectious diseases and is currently administered by the CDC (see Section 3.2).

In 1996, the Foodborne Diseases Active Surveillance System (FoodNet) was established as the foodborne disease component of the CDC's Emerging Infections Program (EIP). FoodNet is collaborative effort between the CDC, the U.S. Food and Drug Administration (FDA), the U.S. Department of Agriculture (USDA), and ten EIP sites. Initially, FoodNet collected data on the incidence of laboratory-confirmed cases of *Campylobacter*, STEC including *E. coli* O157, *Listeria, Salmonella, Vibrio,* and *Yersinia* in five EIP sites (Minnesota, Oregon, and portions of California, Connecticut, and Georgia). The catchment area has since been expanded from those five sites (13.2 million people) to ten sites constituting over 44 million people (approximately 15% of the U.S. population). In addition to bacteria, FoodNet also performs active surveillance for two parasitic organisms, *Cryptosporidium* and *Cyclospora*, and a disease condition called hemolytic uremic syndrome (HUS), which can be an indicator of enterohemorrhagic *E. coli* or other shiga toxin-producing pathogen infection.

3. Foodborne Disease Outbreak Surveillance

Much of our knowledge about the epidemiology of foodborne illness comes from the investigations of outbreaks. Such investigations are initiated by state and local health departments in response to requests by consumers or physicians or because of clustering of reported illnesses. Although clustering is typically defined as increased spatial density of cases, it may also be defined as increased incidence of cases from which bacterial isolates are genetically identical. Prior to 2001, outbreaks were reported to the CDC through the Foodborne Disease Outbreak Surveillance System. However, in 2001, the CDC implemented the Electronic Foodborne Outbreak Reporting System (eFORS). Reports filed through eFORS contain data on demographics of the cases, a description of the outbreak, proposed etiology and food source. Use of eFORS has resulted in a substantial increase in the number of reported outbreaks. Note: In 2009, eFORS was renamed the National Outbreak Reporting System (NORS) to reflect the added ability to report waterborne, zoonotic, and person to person transmission of enteric diseases.

The CDC has published guidelines for the confirmation of foodborne outbreaks caused by several etiologic agents.[2] Table 3 contains some examples of guidelines for a few pathogens. In order to confirm the etiology of an outbreak, specific criteria must be met. An outbreak of *B. cereus* emetic-type illness, for example, is considered confirmed if the organism is isolated from at least two cases but not from controls or if the organism can be found in numbers greater than 10^5/g in the implicated food.

Summaries of the numbers of outbreaks and outbreak-related cases during a 12-year period are shown in Table 4. The figures come from a report from the Center for Science in the Public Interest (CSPI) that compiles CDC outbreak reports along with state outbreak reports and information from scientific and medical journals and newspaper articles. These numbers represent only a small, unrepresentative portion of the actual foodborne illness in the United States, because most outbreaks go unrecognized and because most foodborne illnesses are sporadic. Several factors determine the likelihood that any given outbreak will be recognized and investigated:

1. Size of the outbreak. Larger outbreaks are more likely to be recognized and investigated. Furthermore, larger outbreaks are most likely to result in useful data on etiology and food source. A study of outbreaks occurring within the FoodNet catchment area between 1998 and 1999 observed that 37% of outbreaks with ten or more cases had an etiologic agent identified but only 23% of outbreaks with fewer than ten cases had an etiologic agent identified.[3]
2. Severity of illness. Outbreaks of severe illness are more likely to be recognized and investigated. An outbreak of *C. perfringens* diarrhea, which causes relatively mild illness, will likely go unnoticed unless a large number of illnesses occur. Any case or outbreak of botulism, on the other hand, is likely to come to the attention of public health authorities. During the years from 1990 to 2002, the average size of *C. perfringens* outbreaks was 62 cases, whereas that of botulism outbreaks was just 4 cases (Table 4).
3. Incubation period. A short incubation period increases the likelihood that an outbreak will be recognized and a vehicle implicated. Illness due to *S. aureus*, for example, may be relatively easy to recognize as a common-source problem because of its short incubation period (usually 2–4 h). An outbreak of listeriosis, however, may go undetected because its incubation period is several weeks.
4. Setting. Outbreaks that occur in groups of persons that are clustered geographically are more likely to be recognized. Outbreaks occurring in schools or camps, for example, are more likely to be recognized than outbreaks occurring in the community. However, the active surveillance within the FoodNet catchment area and the availability of molecular typing methods have increased the ability to detect outbreaks that are not geographically clustered. Several studies have utilized pulsed-field gel electrophoresis to identify multi-state outbreaks, which otherwise might not have been detected.[4–6]
5. Ease of diagnosis. The identification of certain organisms, such as vibrios or STEC, requires special techniques that may not be routinely performed when physicians request stool cultures. For this reason, outbreaks of these organisms may not be recognized.
6. Resources available to the local and state health departments. Even large outbreaks can go unrecognized if health departments are unable to devote resources to investigating them. A 1994 outbreak of *Salmonella* serotype Enteritidis involving tens of thousands of cases in over 30 states served to highlight this. Although this outbreak was huge by anyone's standards, the cases were widely dispersed geographically, and it was not immediately apparent that an outbreak was occurring. It was identified only because the Minnesota State Health Department had an aggressive program of serotyping *Salmonella* isolates sent to them, which allowed them to detect the sudden increase in one specific serotype.

There are several limitations of the current system for reporting outbreaks of foodborne disease.[3,7] First, not all outbreaks are included in the surveillance report. Outbreaks occurring on cruise ships, resulting from indirect transmission via contaminated surfaces or from foods eaten outside of the United States are excluded. Furthermore, the classification of food vehicles does not account for multi-ingredient foods (e.g., contained milk can be consumed independently or as an ingredient in a myriad of dairy products). Since the true numbers of outbreaks and cases are probably underestimated to a high degree by such a system, it cannot be used to estimate incidence. Also, because the degree of underreporting is not consistent from pathogen to pathogen, data from this system cannot be used to draw conclusions about the *relative* incidence of these illnesses. Trends are not always reliably noted by this system either; a decrease in the total number of foodborne out-

Table 3. Criteria for Confirmation of Foodborne Outbreaks Due to *B. cereus, C. perfringens, S. aureus, V. cholerae*, and *V. parahaemolyticus*[a]

Etiologic agent	Incubation period	Clinical syndrome	Confirmation
B. cereus			
Emetic-type illness	1–6 h	Vomiting, sometimes diarrhea	Isolation of organism from stools of ≥2 ill persons and not from stools of controls OR Isolation of $\geq 10^5$ organisms/g from epidemiologically implicated food, provided specimen properly handled
Diarrheal illness	6–24 h	Diarrhea, abdominal cramps, sometimes vomiting (fever is rare)	(Same as above)
C. perfringens	6–24 h	Diarrhea, abdominal cramps (vomiting and fever are uncommon)	Isolation of $\geq 10^6$ organisms/g in stool of ≥2 ill persons, provided specimen properly handled OR Demonstration of enterotoxin in stools of ≥2 ill persons OR Isolation of $\geq 10^5$ organisms/g from epidemiologically implicated food, provided specimen properly handled
S. aureus	30 min to 8 h; usually 2–4 h	Vomiting and diarrhea	Isolation of organisms of same phage type forming stool or vomitus from ≥2 ill persons OR Demonstration of enterotoxin in epidemiologically implicated food OR Isolation of $\geq 10^5$ organisms/g from epidemiologically implicated food, provided specimen properly handled
V. cholerae, nonepidemic	1–5 days	Watery diarrhea	Isolation of organisms of same serotype from stools of ≥2 ill persons
V. parahaemolyticus	4–30 h	Diarrhea	Isolation of Kanagawa-positive organisms from stools of ≥2 ill persons OR Isolation of $\geq 10^5$ Kanagawa-positive organisms/g from epidemiologically implicated food, provided specimen properly handled

[a]From CDC Surveillance Summaries.[2]

breaks in the mid-1980s, for example, may have been due to the diversion of public health resources to combat the burgeoning acquired immunodeficiency syndrome (AIDS) epidemic.[8]

Given these limitations, it is not surprising that a significant portion (28.3%) of CSPI-collated outbreaks are of unknown etiology (Table 4). Sixty-eight percent of outbreaks reported to the CDC between 1998 and 2002 had an unknown etiology.[7] In many cases, etiologies may have been suspected by the investigators but not confirmed according to the CDC's criteria. A study of outbreaks occurring in FoodNet sites between 1998 and 1999 reported that 71% of outbreaks did not have an etiologic agent identified.[3] Thus, even with increased surveillance capabilities, the challenges of gathering data associated with foodborne outbreaks are daunting. It is possible that there are other etiologic agents that have yet to be discovered. It is also possible that a large portion of these outbreaks are due to viruses, which remain particularly difficult to diagnose.[7]

Nonetheless, information from this system has been invaluable in the identification and removal of contaminated products from the market, the determination of factors contributing to foodborne illness, the development of public health strategies to prevent foodborne illness, the evaluation of effectiveness of regulatory response, and the advancement of our understanding of the pathogenesis and clinical characteristics of foodborne illness.

Table 4. Summary of Confirmed and Suspected Foodborne Outbreaks and Outbreak-Related Cases in the United States from 1990 to 2002[a]

	Total outbreaks	Percent of total	Total cases	Percent of all cases	Cases per outbreak
B. cereus	60	1.5	1,441	1.1	24
C. botulinum	56	1.4	207	0.2	4
C. perfringens	224	5.5	13,951	10.9	62
Campylobacter	75	1.9	2,023	1.6	27
E. coli	228	5.6	7,227	5.7	32
Listeria	11	0.3	319	0.3	29
S. aureus	175	4.3	5,305	4.2	30
Salmonella	975	24.1	42,288	33.1	43
Shigella	68	1.7	4,610	3.6	68
Streptococcus	3	0.1	226	0.2	75
V. cholerae non-O1	4	0.1	20	0.02	5
V. cholerae O1	4	0.1	34	0.03	9

[a]From CSPI Outbreak Alert.[345]

3.1. Surveillance of Sporadic Diarrheal Illness

Prior to 1995, data on sporadic diarrheal illness was largely obtained through passive surveillance systems. The National Notifiable Diseases Surveillance System (NNDSS) collects data on several illnesses that are sometimes foodborne: botulism, brucellosis, cholera, *E. coli* O157:H7, salmonellosis, shigellosis, and typhoid fever. The data provided are numbers of cases, location, and patient demographic characteristics. Because the NNDSS records both sporadic and outbreak-related illnesses, the numbers of cases registered by this system are typically much higher than those recorded by the outbreak surveillance system; in 2003, for example, the outbreak surveillance system reported 3,948 cases of salmonellosis (351), whereas NNDSS reported 43,657 cases of this disease.[9] There is uncertainty in the number of the NNDSS salmonellosis cases that are due to foodborne transmission, although reports suggest this number is 80–95%.[10]

Presently, FoodNet is the primary active surveillance system used to identify sporadic cases of foodborne illness. FoodNet grew out of CDC's Emerging Infections Program (EIP) and has since expanded to ten sites. FoodNet monitors incidence of foodborne disease and uses active laboratory surveillance to collect data on etiology, risk factors, and outcomes of foodborne disease caused by *Campylobacter*, STEC, *Listeria, Salmonella, Vibrio*, and *Yersinia*, and two parasitic organisms, *Cryptosporidium* and *Cyclospora*. FoodNet personnel contact laboratories within catchment areas either weekly or monthly. The 2003 FoodNet rates are presented in Table 5.

Despite the much improved surveillance and data quality, there are still several limitations of the FoodNet methodology, some of which are due to reliance on laboratory-confirmed cases. Similar to passive surveillance, it is believed that case numbers are subject to a very high degree of underreporting. For example, estimates of salmonellosis indicate that the true incidence in the United States is approximately 40 times that reported to the CDC.[10,11] Also, isolation of pathogens does not prove that they cause disease. As discussed later, some bacteria are commensal in the human host. Furthermore, active FoodNet surveillance does not provide data on viral pathogens, since clinical laboratories (on which the system is based) do not routinely screen for foodborne viruses.

In addition to NNDSS and FoodNet, specific surveillance systems are operational and collect data on *Listeria, Vibrio* species, and *E. coli* O157:H7. These systems have

Table 5. 2003 FoodNet Incidence by Pathogen and Site[a]

[a] Adopted from 2003 CDC FoodNet Report.[12]

included active surveillance components as well as case–control studies designed to determine the routes of transmission of such diseases.

4. Etiologic Patterns

Despite previously described methodological limitations, FoodNet has collected the most useful current data on the etiologic patterns of foodborne disease in the United States. The most recent FoodNet data is from 2008.[354]

There were 18,499 laboratory-confirmed illnesses caused by either *Campylobacter*, STEC 0157:H7, non-0157 STEC, *Listeria*, *Salmonella*, *Vibrio Yersinia*, *Cryptosporidium or Cyclospora* among FoodNet sites in 2008.[354] *Salmonella* infections had the highest incidence of 16.2 infections/100,000 population followed by *Campylobacter* and *Shigella* with 12.68 and 3.03 infections per 100,000 population, respectively.[354] Because FoodNet active laboratory surveillance monitors only nine foodborne pathogens, the rank in foodborne morbidity differs from passive surveillance data (Table 4). According to passive surveillance data, *C. perfringens*, *E. coli*, and *S. aureus* are ranked second, third, and fourth in number of cases with bacterial etiology. Observation of incidence data since FoodNet was implemented in 1996 suggests that, in general, incidence there was a decreasing trend in incidence of foodborne disease through 2004, with rates "leveling off" since that time.

Incidence of foodborne illness appears to vary by a number of factors including seasonality, geographic region, and demographic variables. A large proportion of foodborne illnesses are reported during the summer months of June–August.[12] For example, a 2003 CDC FoodNet report stated that approximately half of all *Vibrio* and STEC infections and more than a third of *Salmonella* infections occurred within these 3 months.[12] In contrast, approximately 41% of *Yersinia* infections occurred during winter months.[12] Incidence of foodborne illness also varied by both age and gender with children less than 1 year of age and males typically having higher incidence of infection.[12]

FoodNet has also detected state-specific differences in isolation rates of foodborne pathogens (Table 5). For example, the 2003 CDC FoodNet Final Report shows that California has a high incidence of *Campylobacter*, which has remained consistently high (data not shown) in comparison to other FoodNet sites over the past decade. In contrast, Maryland and Georgia have consistently low *Campylobacter* infection rates. Many hypotheses have been generated as to the cause of this phenomenon, including different food, water, and environmental exposures, and different food processing regulations.[13,14]

Among laboratory-confirmed foodborne disease cases in 2003, 22% were hospitalized and 83 cases died.[12] Thus the case-fatality rate was very low overall other than *Listeria*, which had a 17% case-fatality rate.[12] Case-fatality ratios are generally low for all foodborne pathogens. The majority of deaths that occur are in the elderly or very young. However, *Listeria* is also a problem in the immunocompromised patient as well as in infants and otherwise healthy pregnant women. Hospitalization varied significantly by the infecting organism. Again *Listeria* cases were mostly likely to have been hospitalized (91%).

It is important to note that etiologic patterns may vary throughout the world. These patterns are dependent on many factors, such as food preferences, food preparation, physician and public awareness, and laboratory capabilities. In the United States salmonellosis currently comprises the largest percentage of foodborne illness cases.[15] In England and

Wales *Campylobacter* is the major etiologic agent of foodborne disease.[16] Japan, on the other hand, has very different etiologic patterns, probably related to many of the aforementioned factors. *Vibrio*-related gastroenteritis, first described in that country, is usually the dominant pathogen in foodborne outbreaks.[17] These associations generally reflect the different staples in diets around the world (i.e., higher seafood consumption in Japan, higher meat and poultry consumption in the United States and Europe). Clearly, some of these differences represent ascertainment bias; however, there is little doubt that different patterns exist in different regions of the world.

With this background, let us turn to a consideration of the specific agents *S. aureus, B. cereus, C. perfringens, Vibrio* species, *Aeromonas*, and *Plesiomonas*.

5. *Staphylococcus aureus*

5.1. Historical Background

Although Dack modestly credited others for the discovery of staphylococcal food poisoning, he and his coworkers were the first to prove that this illness was due to toxin production by *S. aureus*.[18] They performed classic experiments in volunteers, demonstrating that culture filtrates of staphylococci isolated from a cream-filled sponge cake that had been the implicated vehicle in a foodborne outbreak could cause gastroenteritis.[19]

It is generally recognized that *S. aureus* exotoxins are responsible for symptoms of skin infections, while ingested enterotoxins cause the diarrhea and vomiting associated with staphylococcal food poisoning. The work on the enterotoxins produced by *S. aureus* has been fundamental to our understanding of this syndrome. Dolman and Wilson.[20] established that antibody to the enterotoxin could be made and, 15 years later, Surgalla et al.[21] showed that there was more than one immunologic type. Casman, Bergdoll, and others characterized the physicochemical properties of these enterotoxins and initially established that there were seven serotypes: A, B, C_1, C_2, C_3, D, and E.[22] To date, as many as 13 other Staphylococcal enterotoxins and staphylococcal enterotoxin-like toxins have been identified through genome analysis.[23,24]

5.2. Microbiology

5.2.1. Biological Characteristics of the Organism. Staphylococci are gram-positive, nonencapsulated, nonmotile, non-spore-forming cocci that usually appear in grapelike clusters, hence the name. They are aerobic and facultatively anaerobic, may be β-hemolytic and catalase-positive, and ferment glucose. The genus *Staphylococcus* contains almost two dozen species that are traditionally divided into two groups on the basis of coagulase production. Coagulase-positive staphylococci are almost always *S. aureus*, although some strains of *S. intermedius* and *S. hyicus* also produce this enzyme.[22] All other species are coagulase-negative, the most important of which are *S. epidermidis* and *S. saprophyticus*.

S. aureus, the usual pathogen in foodborne disease, is capable of producing at least 21 enterotoxins, which share structure and sequence similarities. These known enterotoxins are all short proteins with molecular weights of 24–30 kD, which contain large numbers of lysine, aspartate, glutamate, and tyrosine residues.[24] They are heat stable and resistant to a variety of proteases, including pepsin and trypsin.

Superantigenic activity has been demonstrated for more newly characterized enterotoxins, but rarely emetic activity.[24] The mechanism of emesis-inducing action of staphylococcal enterotoxins is still unknown although their positive charge,[25] cysteine loop structure (found only in some enterotoxins, most notably SEA),[26] and disulfide bond formation[27] have been suggested as a link(s) to emetic activity. Since vagotomy and abdominal sympathectomy in monkeys render them completely immune to the emetic effects of these toxins, their receptor or receptors are probably within the lumen of the gastrointestinal tract. It is not clear what these receptors are or the precise binding sites in enterotoxin proteins with which they interact.[24] The mechanism by which these toxins produce diarrhea is even less well understood; they fail to cause a reaction in rabbit ileal loop assays, though one group has been able to demonstrate fluid secretion in rat small intestine when challenged with staphylococcal enterotoxin B.[28]

A variety of other toxic substances are produced by *S. aureus* that are hemolytic, leukocytic, dermonecrotic, and lethal to animals. All *S. aureus*, by definition, produce a coagulase that causes coagulation of plasma; it is both free and bound to the cell wall. *S. aureus* also produces a fibrinolysin, hyaluronidase, deoxyribonuclease, and various lipases. Many of these substances are physiologically important for the other manifestations of staphylococcal infections, but are beyond the scope of this chapter; the reader is referred to Chapter 34 of this book for further information.

S. aureus is not the only species in this genus that is capable of producing staphylococcal enterotoxins. Strains

of *S. intermedius, S. hyicus*, and *S. epidermidis* have been shown to produce these.[22] The latter has been implicated in a foodborne outbreak.[29] It is important to note also that not all *S. aureus* strains are enterotoxigenic. The frequency of enterotoxigenic strains in foods varies from one study to another.

5.2.2. Laboratory Diagnosis. The medium currently recommended by the FDA for isolation and enumeration of large quantities of staphylococci from food is an egg yolk–tellurite–glycine–pyruvate agar ("Baird-Parker agar").[30] Coagulase-positive staphylococci produce a zone of clearing in egg-yolk emulsion and reduce tellurite salt to tellurium, causing the staphylococci to form black colonies. Mannitol as the sole or major source of carbon in the medium, along with a high NaCl content, can also be used in a selective medium, although such conditions may inhibit the growth of heat-stressed staphylococci.[31] It has been shown that this growth inhibition can be overcome with catalase.[25] Small numbers of *S. aureus* (expected in outbreaks where little source is available or competing species are high) are isolated using the most probable number method, in which tryptic soy broth is inoculated with sample to increase enumeration of *S. aureus* prior to streaking on Baird-Parker agar. Coagulase tests can be done in a tube using brain heart infusion broth and rabbit plasma containing EDTA. A clotting reaction of 4+ is recommended for confirmation of *S. aureus.*[30] An outbreak in Japan due to uncharacteristic egg-yolk reaction-negative *S. aureus*[32] suggests that more than one biochemical procedure should be used to confirm *S. aureus* species. However, most recommended tests are insufficient in delineating enterotoxigenic and nonenterotoxigenic staphylococci.[30]

Demonstration of staphylococcal enterotoxin is an important tool in outbreak investigations, since reheated food may contain toxin but no viable staphylococci. Several methods have been described, including enzyme-linked immunosorbent assay (ELISA),[33,34] enzyme immunoassay (EIA),[35] latex agglutination,[34] and immunoblot.[36] Several commercial kits have been formulated for toxin detection.[37] The method used should be capable of detecting concentrations of less than 1 ng/g of food, since a dose of 1 μg toxin/100 g food is sufficient to produce symptoms.[38]

Oligonucleotide probes, multiplex polymerase chain reaction (PCR), microarray assays, pulsed-field gel electrophoresis (PFGE), and plasmid restriction analysis are also used to demonstrate the presence of toxin genes in staphylococcal isolates.[23,39–44] These DNA-based techniques are used infrequently, however, in areas where resources are limited.

5.3. Descriptive Epidemiology

5.3.1. Prevalence and Incidence. Table 4 summarizes *S. aureus* outbreak data from the United States from 1990 to 2002. There are approximately 30 cases per outbreak and approximately 15 outbreaks per year, with *S. aureus* contributing 4.2% of all foodborne cases in the United States. A summary of annual foodborne pathogen-specific estimates in England and Wales from 1996 to 2000 showed that *S. aureus* contributes to only 0.5% of total foodborne illness.[16]

5.3.2. Epidemic Behavior and Contagiousness. Staphylococcal foodborne outbreaks are characterized by explosive onset between 30 min and 8 h after consumption of a contaminated vehicle (usually 2–4 h, depending on the amount of toxin ingested).[19,45] Attack rates are usually quite high, since very small quantities of enterotoxin can cause illness.[19] Secondary cases are uncommon.

5.3.3. Geographic Distribution. There can be geographic clustering of cases. Because outbreaks are usually related to food contamination from human staphylococcal carriers, one generally finds localized cases disseminating from one person who has prepared meals for people in confined spaces (such as prisons or nursing homes). If contamination occurs closer to the farm end of the farm-to-fork spectrum (i.e., in products such as milk), contamination and hence outbreaks may be more widespread.

5.3.4. Temporal Distribution. Outbreaks from staphylococci can occur at any time of the year, but most outbreaks are reported during the warm weather months.[45,46] This is probably because higher ambient temperatures provide better conditions for bacteria to multiply when foods are contaminated.

5.3.5. Age, Gender, Race, and Occupation. There are no age, gender, racial, or occupational characteristics that are peculiar to staphylococcal food poisoning.

5.3.6. Occurrence in Different Settings. Staphylococci are carried by such a high percentage of the population that almost any food-preparation setting can be involved. Approximately 60% of the population are intermittent carriers of *S. aureus* and 20% are thought to be persistent carriers.[47] Most reported outbreaks are from large gatherings, i.e., prisons, schools, group picnics, clubs, and restaurants. There have been reports of hospital-acquired *S. aureus* infections that have caused acute outbreaks of foodborne gastroenteritis.[48]

5.3.7. Foods Implicated in Outbreaks. For several years after the recognition of staphylococcal food poisoning, cream-filled baked goods were the leading source of this illness in the United States. In recent decades, other proteinaceous foods, especially meat and meat products, have predominated. In the United States and Great Britain, ham

has been the most commonly implicated vehicle, which may be in part due to its relatively high salt content; *S. aureus* is very tolerant of salt, which increases its resistance to heat. In Japan *S. aureus* food poisoning is caused mostly by processed foods composed of rice, rather than raw meat and meat products.[49] Milk and milk products are responsible for most *S. aureus* cases in France.[50] Both raw and pasteurized milk have been implicated as vehicles in *S. aureus* foodborne outbreaks in other countries. Other vehicles have included potato salad, egg salad, cheese, canned foods, and seafood. Improper holding temperature is the most common behavioral factor in *S. aureus* outbreaks.[8]

5.4. Mechanisms and Routes of Transmission

The single most important source of staphylococcal contamination in foods is humans, where this organism can commonly be found on mucous membranes, skin, or nasal carriage.[47,48]

As the number of methicillin-resistant *S. aureus* (MRSA) nosocomial and community-acquired infections grows, there may be a subsequent increase in MRSA gastroenteritis cases. MRSA strains are also capable of producing enterotoxins, however, these strains are likely to go unnoticed because *S. aureus* isolates from foodborne outbreaks may not be tested for antibiotic susceptibility.[48] MRSA strains are not expected to be more clinically virulent since *S. aureus* gastroenteritis is self-limiting.

In most outbreaks, food has been contaminated after processing by food workers who are carriers of enterotoxin-producing strains of staphylococci.[51] It was once observed that many of these workers had visible lesions on the hands or nose. This is an uncommon finding now, although it is true that *S. aureus* of the same phage type as that in the contaminated food can be found in food handlers in roughly two-thirds of outbreaks.[46] These handlers are generally asymptomatic carriers.

Even though many animals and animal carcasses are contaminated before processing, this usually does not result in food poisoning. Competitive growth from other flora usually contains the slower-growing staphylococci. One exception to this is milk, which can be heavily contaminated with *S. aureus* when obtained from a mastitic animal.[22]

5.5. Pathogenesis and Immunity

5.5.1. Pathogenesis. There are three prerequisites for staphylococcal food poisoning to occur: (1) contamination of a food with enterotoxin-producing staphylococci; (2) a food that provides the necessary growth requirements for the organism; and (3) appropriate time and temperature for the organism to multiply. To date, enterotoxins A through J have been the most commonly implicated enterotoxins in outbreaks of staphylococcal food poisoning. This may change, however, as tests are developed to identify more recently discovered enterotoxins.

5.5.2. Immunity. It is not clear whether immunity develops in this illness. Although attack rates are not usually 100% in outbreaks, many individuals may not consume the enterotoxin or enough of the implicated vehicle. In outbreaks where small groups are involved in which everyone consumes the implicated food, attack rates are very high (80–100%). Early attempts to "immunize" man or develop "tolerance" to toxin were not successful when broth filtrates of toxin-producing staphylococci were administered by mouth.[52]

Clearly, individuals have differing sensitivity to enterotoxin; in one investigation using volunteers, as little as 0.5 ml of a filtrate could cause illness in one person, whereas 13 ml administered to another individual caused no symptoms. Whether this is a case of immunity or physicochemical sensitivity of a receptor site is not clear. Whether immunity from one toxin confers cross-immunity to others has not been determined.

5.6. Patterns of Host Response

5.6.1. Clinical Features. The symptoms of staphylococcal food poisoning are primarily profuse projectile vomiting, nausea, and abdominal cramps, often followed by diarrhea.[37,53–55] In severe cases, blood may be observed in the vomitus or stool.[56] Rarely, hypotension and marked prostration occur. Fatalities are unusual, and recovery is complete in 1–3 days in healthy individuals.[38,57] Fever is not a common accompaniment, but may be present if dehydration is severe.

5.6.2. Diagnosis. Staphylococcal food intoxication should be considered in anyone who presents with severe vomiting, nausea, cramps, and some diarrhea. A history of ingesting meats of high salt content may be helpful. Usually, the best epidemiological clue is the short incubation period (usually 2–4 h) and the absence of fever. Of the bacterial foodborne diseases, only *B. cereus* emetic-type illness has a similar presenting illness with a short incubation period. This disease is so closely allied with fried rice as to allow an easy distinction.

6. *Bacillus cereus*

6.1. Historical Background

One of the first outbreaks implicating an aerobic spore-forming organism was described by Lubenau[58] in 1906, in which 300 inmates of a sanitorium developed a diarrheal

illness from meatballs contaminated with an organism labeled *Bacillus peptonificans*. This isolate closely resembled what is today considered typical of *B. cereus*. During the several decades following this description, other European investigators cited similar aerobic spore-forming bacilli in food poisoning involving vanilla sauce, jellied meat dishes, and boiled beef. However, it was not until Hauge's[59] description of four separate Norwegian outbreaks in 1955 that *B. cereus* was conclusively implicated as a cause of diarrheal illness. These outbreaks, all linked to vanilla sauce containing large numbers of *B. cereus*, produced an illness characterized by profuse, watery diarrhea, abdominal pain, nausea, but rarely vomiting or fever. The incubation period averaged 10–12 h, with illness resolving within 12–24 h. Subsequent experiments in which Hauge and other volunteers ingested vanilla sauce inoculated with *B. cereus* substantiated the role of this organism.[59]

After Hauge's report, outbreaks of similar illness were described in northern and eastern Europe, particularly in the Netherlands and Hungary. The first well-documented outbreak of gastrointestinal disease in the United States was reported by Midura et al.[60] in 1970.

In 1974, another form of *B. cereus* illness was recognized that involved fried rice.[61] This illness was distinctly different from those previously described, in that the incubation period was shorter, ranging from 1 to 6 h, and the illness was primarily vomiting (although some patients had diarrhea as well). Although this condition closely resembled staphylococcal food poisoning, *B. cereus* was recovered from the fried rice.

Since this report, it has become accepted that *B. cereus* is capable of producing two distinct foodborne syndromes. The emetic illness, usually associated with rice-based dishes, is caused by ingestion of a preformed heat-stable toxin that is produced by the bacteria in the food. The diarrheal illness, associated with a large variety of foods, has a longer incubation period and is caused by at least one of two heat-labile toxins that are produced by the bacteria in the intestine.

6.2. Microbiology

6.2.1. Biological Characteristics of the Organism. *B. cereus* is a gram-positive, catalase-positive, aerobic spore-forming rod that is mobile by means of peritrichous flagella. Most strains are β-hemolytic.

Strains of *B. cereus* produce a wide variety of exotoxins, but only two categories appear to be important in the pathogenesis of food poisoning: the "diarrheogenic enterotoxin" and the "emetic toxin." Early studies of enterotoxin suggested that there was one diarrheogenic toxin, but since then, three enterotoxins have been characterized. Two enterotoxins are associated with diarrheal syndrome: the three-component hemolysin BL toxin (HBL) and the three-component nonhemolysin enterotoxin (Nhe). It is not known how much a third single component enterotoxin[62] contributes to food poisoning.[63,352] HBL is not only hemolytic, but also induces fluid accumulation in rabbit ileal loop and necrosis of villi, and forms pores in eukaryotic cell membranes.[64,65] Studies indicate that Nhe shares some sequence and structural homologies with HBL.[66] Strains and other *Bacillus* species can produce one or both of the multi-component enterotoxins. At present, it is unclear how important each toxin is to the epidemiology of food poisoning. A number of other possible enterotoxins have been reported but their biological activity has not been defined.[66]

The emetic toxin, which has in recent years been named cereulide, was first isolated from a strain implicated in an outbreak of vomiting-type illness. Cereulide is a cyclic peptide composed of three repeats of four amino acids, and has a molecular weight of 1.2 kD. In contrast to the diarrheal toxins, cereulide is highly stable, resisting heat, pH and proteolysis. It is thought to bind the 5-HT3 receptor and stimulate the vagus afferent.[67] In experiments using animal models (rhesus monkey and Asian musk shrew), the emetic dose of cereulide was found to be between 9 and 12 μg/kg.[68,69] Production of emetic toxin is linked with temperature [highest elaboration occurring between 12 and 15°C[70]] and quite possible sporulation.[71] Cases of liver failure caused by *B. cereus* food poisoning,[72,73] has led to the discovery that the emetic toxin is a mitochondrial toxin.[72]

6.2.2. Laboratory Diagnosis. *B. cereus* can be cultured on blood agar, grown aerobically at 37°C. Isolates from blood agar form flat, granular β-hemolytic colonies, resembling "ground glass". The FDA recommends use of a mannitol–egg yolk–polymyxin agar with incubation for 24–48 h at 30°C.[74] This medium utilizes mannitol (which *B. cereus* cannot catabolize), the selective agent polymixin B, and a lecithinase reaction on the egg yolk for identification of *B. cereus* isolates. Chromogenic media are also being utilized. Enumeration of *B. cereus* can be performed either by direct plating or, if expected numbers are less than 1,000/g, by most probable number methods.[74] *B. cereus* has 16S and 23S ribosomal sequences that are nearly identical to sequences in *B. thuringienisis*, *B. mycoides*, and most importantly *B. anthracis*. Need for proper differentiation of *B. cereus* from *B. anthracis* has become increasingly important in the post-September 11th era. Traditionally, tests for motility, rhizoid growth, hemolytic activity, and protein toxin crystals were used to distinguish *B. cereus* from other species.[74] However, recent experiments have indicated these tests may not be adequate.[75–77]

Animal models such as monkey feeding and rabbit ileal loop assays have been used for detection of the diarrheagenic toxin as have cytotoxic cell assays. However, the validity of these assays needs further assessment. Commercial kits have been developed that employ reverse passive latex agglutination and enzyme immunoassay methods.[66] The diarrheogenic toxin can also be demonstrated in *B. cereus* cells by PCR or plasmid profile analysis.[78] However, even when sought, the enterotoxin is often not found because of the instability of this molecule, which is rapidly degraded by proteolytic enzymes.[79] There are as yet no commercially available immunoassays for detecting emetic toxin. Typically, culture filtrates from emetic food-poisoning samples are tested using a HEp-2 vacuolation assay, a sperm-based bioassay, or LC-MS analysis.[68] Recently, a PCR assay was developed against a gene specific to emetic toxin-producing *B. cereus* strains, which allows rapid detection of bacteria during food outbreaks.[43,73]

6.3. Descriptive Epidemiology

6.3.1. Prevalence and Incidence. Because *B. cereus* food poisoning is not a reportable disease and misreporting may occur as symptoms are mistaken for those caused by *C. perfringens* (diarrheal) or *S. aureus* (emetic), the true incidence of *B. cereus* illness is unknown. As with many foodborne pathogens, disease due to this organism often goes undiagnosed and unreported, mainly due to mild symptoms and short disease duration. Outbreak surveillance data from 1990 to 2002 (Table 4) show that this pathogen accounts for 1.5% of foodborne outbreaks in the United States. The average size of these outbreaks is 24 cases.

In Europe, *B. cereus* has accounted for a larger portion of outbreaks, most of which are of the diarrheal type. In Norway, for example, 33% of all food-poisoning cases from 1988 to 1993 were due to this organism.[80] In Hungary, *B. cereus* was the third most common cause of foodborne illness from 1960 to 1968.[81] The relatively high incidence was attributed to a preference in the Hungarian population for well-spiced meat dishes. The spices used were found to contain large numbers of *Bacillus* spores. Poor postcooking storage procedures allowed the spores that survived cooking to germinate. In Japan, it is the emetic type that is reported more frequently.[81]

6.3.2. Epidemic Behavior and Contagiousness. In the original description by Hauge,[59] 82% of individuals who ate the incriminated meal were affected. Of the 19 who were not ill, 11 had not eaten the dessert (implicated vehicle), and 8 had eaten only a small quantity. Other reported outbreaks have indicated attack rates from 50 to 75%.[82,83] In the reported vomiting-type outbreaks, virtually all individuals who consumed contaminated food became ill. There is minimal risk of secondary cases, since heavy contamination of the implicated vehicle is required.

6.3.3. Geographic, Temporal, Age, Gender, Racial, and Occupational Distribution. *B. cereus* food poisoning has not shown any geographic or temporal distribution. Children and elderly may become more severely affected and require hospitalization. There does not appear to be any gender, racial, or occupational predisposition.

6.3.4. Occurrence in Different Settings. Most reports of diarrheal illness have taken place in institutional settings (schools, hospitals, and others). This may be a reporting artifact, since foodborne outbreaks are more easily recognized in confined populations.

6.3.5. Other Factors. The clear-cut association between the vomiting syndrome and fried rice deserves emphasis. The first three reports of outbreaks of emetic-type *B. cereus* illness in the United States[84] and the report by Mortimer and McCann[61] of five outbreaks in Great Britain implicated fried rice as the vehicle. This association has been attributed to the method used to prepare this food in Chinese "takeout" restaurants (see below). Other foods implicated in these types of outbreaks are pasta salad, mayonnaise, and turkey loaf, and hot chocolate from vending machines.

The diarrheal illness has also been caused by a large variety of foods including barbequed pork, boiled beef, sausage, chicken soup, macaroni and cheese, vanilla sauce, and puddings.

6.4. Mechanisms and Routes of Transmission

The frequent isolation of *B. cereus* in agricultural products is due to its abundance in soil. Because it comprises the natural flora of many foods, *B. cereus* has been found in about 25–50% of foodstuffs sampled, including cream, pudding, meat, spices, dry potatoes, dry milk, infant foods, spaghetti sauces, and rice.[85–87] Contamination of the food product generally occurs prior to cooking. If the food is prepared in such a manner that the temperature is maintained at 30–50°C, vegetative cell growth will occur. Spores can survive extreme temperatures, and when allowed to cool relatively slowly, they will germinate and multiply.[88] For these reasons it is recommended that food be maintained at 60°C or higher and if it is to be stored, cooled rapidly to below 8°C.

The association of the emetic-type illness with fried rice can be attributed to the method in which this food is prepared in Chinese restaurants. Rice is first boiled in bulk and then stored at room temperatures for periods as long as 3 days. Chefs in these institutions are usually reluctant to refrigerate the rice because this causes it to clump. The rice is then rapidly fried when needed with a mixture containing

beaten eggs. The heat produced during this second cooking is insufficient to destroy the heat-stable emetic toxin. Studies have found viable *B. cereus* in up to 93% of specimens of boiled rice, though the number of organisms is usually less than 10^5/g.[87–89]

Human fecal carriage is not believed to play a role in transmission of *B. cereus*, though this organism can transiently colonize the intestinal tract for periods of up to 4 days.[90] The isolation rate of *B. cereus* in the stool of asymptomatic individuals can be as high as 40% and is thought to be due to the high prevalence of this species in foods.[91,92] The European Food Safety Authority has even approved probiotic use of *B. cereus* strains that produce minute amounts of toxin.

6.5. Pathogenesis and Immunity

6.5.1. Pathogenesis. *B. cereus* food poisoning is toxin-mediated in both the diarrheal form and the emetic form.[84] Whether the diarrheogenic, heat-labile enterotoxin is actually ingested or produced in vivo is not known; there are, however, several pieces of evidence to suggest that the latter mechanism may be operative. The incubation period in the diarrheal illness is longer than might be expected for preformed toxin (>6 h; average 12 h), and a large inoculum (10^5–10^8 cells/g) is required to cause illness, suggesting a requirement for intestinal colonization.

The emetic illness is presumptively caused by preformed toxin that is heat stable. The short incubation period and high attack rate provide support for this pathogenic mechanism.

6.5.2. Immunity. Our knowledge of immunity to either of these syndromes is largely uncharted. Antiserum to the diarrheogenic enterotoxin introduced into the rabbit ileal loop model along with the toxin can prevent fluid accumulation; no careful studies in humans have been performed. There are many serotypes of *B. cereus*, but it is not known whether the various enterotoxins have immune cross-reactivity. The emetic toxin is poorly antigenic [when repeatedly challenged with this, rhesus monkeys develop no resistance to its action[79]] but may still have immunomodulating properties (inducing apoptosis in natural killer cells).[93]

6.6. Patterns of Host Response

6.6.1. Clinical Features. The initial report by Hauge[59] described the diarrheal illness of *B. cereus*, and his findings are consistent with what we know today. Illness begins after a 10–12 h incubation period is characterized by diarrhea (96%), abdominal cramps (75%), and vomiting (23%). Fever is uncommon. The duration of illness has ranged from 20 to 36 h, with a median of 24 h.[59,84]

The emetic form of the illness has a short incubation period that varies from 1 to 6 h and the predominant symptoms of vomiting (100%) and abdominal cramps (100%). Diarrhea is present in only one-third of affected individuals.[84] The duration of this illness has ranged from 8 to 10 h, with a median of 9 h. In both types of illness, the disease is usually mild and self-limited.

6.6.2. Diagnosis. The diagnosis of *B. cereus* food poisoning should be considered in any individual who has diarrhea without fever in association with lower abdominal cramps. The incubation period varies from 6 to 24 h. The easiest way to make the diagnosis is by culture of the incriminated food product. The disease caused by *C. perfringens* is so similar to the diarrheal form of *B. cereus* that they cannot be differentiated clinically or epidemiologically; culture methods are required. The emetic form of the disease should be suspected in an individual presenting with nausea and vomiting 1–5 h after consumption of a farinaceous food, especially fried rice. The clinical picture is indistinguishable from that of *S. aureus* food poisoning.

Because *B. cereus* can be found in many foodstuffs, this organism should only be considered significant if present in the incriminated food item in numbers of 10^5 or more per gram.[7] Similarly, since *B. cereus* can sometimes be found in the stools of healthy persons[91,92] isolation of the organism from feces may not be a suitable confirmation unless negative stool cultures are obtained from an appropriate control group. As a result, phage typing of *B. cereus* has emerged as a reliable resource in epidemiological investigations allowing one to trace isolates to implicated foods/sources.[94,95] PFGE techniques are used as well.[96] Serotyping has also proven useful in epidemiologic studies. Forty-two serotypes have been identified based on classification of spore, somatic, and flagellar antigens. Twenty-three of the 42 serotypes are associated with *B. cereus*-related disease.[66] Of 200 outbreak-related *B. cereus* isolates from 11 different countries between 1971 and 1986, 91% were typeable by this system.[81] Of these, 127 (64%) were H-type 1, a serotype found in 23% of cooked rice. H-1 has been positively correlated with production of emetic toxin,[67,81,97] along with types 5, 8, 12, and 19.[66] The flagellar (H) antigens most commonly associated with diarrheal food poisoning are 1, 2, 6, 8, 10, 12, and 19.[66]

7. *Clostridium perfringens*

7.1. Historical Background

C. perfringens was first recognized and confirmed in the United States as a foodborne pathogen in 1945 by

McClung,[98] who studied four outbreaks of diarrhea related to the consumption of chickens steamed 24 h prior to consumption. *C. perfringens* was isolated from the cooked chickens. Prior to this discovery, workers in Europe had also recognized that gravy contaminated with anaerobic spore-forming bacilli, including *C. perfringens*, had caused gastrointestinal illness in children.[98,99]

Shortly after McClung's discovery, filtrates from strains of *C. perfringens* were administered by mouth to human subjects.[100] Cramps and diarrhea occurred in some individuals, but the incubation period was short: 45–80 min. Living cultures induced cramps and bloating in 4 h and diarrhea several hours thereafter. Hobbs et al.[101] elegantly confirmed these results and outlined the epidemiological features of the disease in Great Britain in 1953.

The other major discovery in the late 1940s was the outbreak of a severe and often lethal intestinal disease-labeled enteritis necroticans or "Darmbrand" that affected over 400 people in Germany;[102] this outbreak was similar to others described later in New Guinea and termed "pig bel"[103] (see Section 7.7). Both conditions were due to *C. perfringens*. The strains were originally designated *Clostridium welchii* type F but were later reclassified as *C. perfringens* type C.

Up to this time, all foodborne outbreaks were felt to be due to heat-resistant *C. perfringens*. Several investigators in the late 1960s confirmed that nonhemolytic and β-hemolytic, heat-sensitive strains could cause food poisoning.[104]

Investigations in the late 1960s and early 1970s provided convincing evidence that the pathogenesis of *C. perfringens* food poisoning is due to enterotoxin production while cells are sporulating. Furthermore, enterotoxin can be demonstrated in *C. perfringens* types A, C, and D. The toxins of types A and C are quite similar with regard to physicochemical properties.

7.2. Microbiology

7.2.1. Biological Characteristics of the Organism. Clostridia are gram-positive, spore-forming anaerobes. Although all species grow better under anaerobic conditions, *C. perfringens* is remarkably aerotolerant and may survive exposure to oxygen for as long as 72 h. This organism has a characteristic "boxcar" appearance on Gram-stained slides and, unlike most *Clostridium* species, is nonmotile. The spores produced by this organism are oval, subterminal, and only rarely seen in clinical specimens.

C. perfringens produces at least 15 toxins that contribute to its virulence. The species is divided into five types, A–E, on the basis of four major toxins, α, β, ε, and ι and enterotoxin genes. Type A is the agent of classic *C. perfringens* food poisoning. Almost all strains of this type isolated from outbreaks produce α-toxin (a lecithinase).[105,106]

The best characterized enterotoxin identified thus far is CPE, a heat-labile protein with a molecular weight of approximately 35 kD. CPE is produced by type A isolates. A review by McClane suggests that CPE is elaborated in the cytoplasm of *C. perfringens* during its sporulation in the intestine.[107] Lysis of *C. perfringens* at the end of sporulation releases CPE into the intestinal lumen, where it binds receptors on the surface of intestinal epithelial cells.[107] CPE is thought to be pore-forming, subsequently altering membrane permeability and compromising tight junction structure and function.[107] The role of this toxin in producing diarrheal illness was confirmed by feeding cell-free filtrates to volunteers. Of 15 persons who consumed filtrates from toxin-producing strains, four developed diarrhea, whereas none of 16 persons fed filtrates from toxin-negative strains developed illness. The incubation period for illness in these volunteers was 2–2.5 h. Similar results have been obtained in experimental animals.[108,109] Another type A enterotoxin (θ-toxin) has been discovered to induce food-related diarrhea in humans and animals.[110] The significance of this pore-forming cytolysin is questionable, however *C. perfringens* strains with inactivated *cpe* genes were unable to affect rabbit ileal loops,[111] suggesting that CPE is required for induction of diarrheal symptoms. A β2-toxin (CPB2) has been thought to have diarrheagenic properties due to its high prevalence in diarrheic piglets.[112] Although β2-toxin has not been associated with human illness yet, it has been found produced by type A *C. perfringens* gastrointestinal disease isolates containing the *cpe* gene on plasmids.[113]

C. perfringens is ubiquitous in the environment. It can be found in almost any soil, where it performs its principal role in nature: the breakdown of organic waste. A 2004 study found that 1.4% of 900 samples of non-outbreak American retail foods are contaminated with *cpe* gene-containing *C. perfringens* isolates.[114] However, another study found no *cpe*-positive *C. perfringens* isolates in 131 retail samples.[115] Both *cpe*-positive and *cpe*-negative organisms are also a common component of the gastrointestinal tract of healthy humans and animals; surveys of asymptomatic individuals show that it can be isolated from almost any stool sample if enrichment techniques are used, but it is usually present at concentrations less than 10^4 CFU/g, except in the elderly, where it frequently exceeds 10^6 CFU/g. The lowest numbers are found in vegetarians, which may indicate that animals are a source of pathogenic *C. perfringens* strains. Because this organism is part of the human natural flora and isolation is complicated by the presence of a large number of *cpe* gene-negative cells,[116–118] enumeration of *cpe* gene-positive spores in the feces and suspected food is recom-

mended when attempting to confirm *C. perfringens* as the cause of a foodborne outbreak.[119] Interestingly, the *cpe* gene has been found not only on the chromosome of *C. perfringens* food-poisoning isolates, but on the plasmid of non-foodborne gastroenteritis-causing isolates.[120,121] Although there are exceptions to this observation,[122,123] it has been useful in epidemiological investigations.

7.2.2. Laboratory Diagnosis. The selection of media is dependent on whether the sample is fecal or food. The FDA-recommended culture medium is the egg yolk–free tryptose–sulfite–cycloserine agar.[124] It allows sulfite-reducing clostridia to form black colonies and inhibits other facultative anaerobes.[125,126] Colonies can then be selected for nitrate reduction, non-motility, liquefaction of gelatin, and glucose fermentation.[125]

Three other characteristics are of use in the isolation of *C. perfringens*: a dual zone pattern of hemolysis on blood agar plates, opalescence (precipitation) on egg-yolk media, and "stormy fermentation" in milk media. On blood agar, *C. perfringens* colonies are surrounded by a narrow inner ring of incomplete hemolysis due to θ-toxin, and a much wider outer ring of complete hemolysis due to α-toxin. On egg-yolk agar, colonies produce opalescence, termed the "Nagler reaction," which is due to the presence of α-toxin. Presumptive identification of *C. perfringens* can be achieved with an egg-yolk agar plate, which is partly coated with *C. perfringens* α-antitoxin, which inhibits the opalescence. Stormy fermentation in milk media is characteristic of *C. perfringens*. Vigorous lactose fermentation produces both acid, which coagulates the casein in the milk medium, and large amounts of gas, which breaks apart the clot.[127] For enumeration, tryptose–sulfite–cycloderine (TSC) agar is recommended.[128]

None of these reactions are 100% sensitive or specific for *C. perfringens*. Other *Clostridium* species produce lecithinases that are inhibited by the α-antitoxin. Similarly, other species ferment lactose rapidly and produce stormy fermentation. Furthermore, many outbreak-related strains do not produce a double zone of hemolysis. Several lecithinase-negative strains have been isolated from outbreaks in the United Kingdom.[129]

Most enrichment techniques do not distinguish between causative and non-causative strains, and therefore molecular epidemiologic methods are recommended during outbreak investigations.[130] Labs with readily available molecular technology have used PCR of the *cpe* gene.[131] The observation that food-poisoning isolates carry a chromosomal *cpe* gene, while non-foodborne gastrointestinal (GI) disease isolates have a plasmid *cpe* gene has motivated the use of a multiplex PCR assay.[132] PFGE with *Sma*I and *Apa*I enzymes has also been used.[117,133] However, other studies have shown that enterotoxigenic data must accompany PFGE in order to increase the validity of etiologic analysis.[116] Fecal enterotoxins can be detected by ELISA,[134] counterimmunoelectrophoresis, and reversed passive latex agglutination assays.[116,135,136] DNA probes,[137] ribotyping,[118] and plasmid prophiles[138,139] can also be used to test enterotoxigenicity of strains of *C. perfringens* isolated from feces and food during outbreaks. A newly developed method, hydrophobic grid membrane filter-colony hybridization (HGMF-CH), can be used for enumeration and *cpe* detection using both biochemical and molecular hybridization techniques.[119]

7.3. Descriptive Epidemiology

7.3.1. Prevalence and Incidence. Almost all of our knowledge of the epidemiology of *C. perfringens* food poisoning comes from the study of outbreaks. Table 4 summarizes these data for the United States from 1990 to 2002. Given that the diagnosis of *C. perfringens* food poisoning is difficult to confirm because of the ubiquity of the organism in foods and stools, it is likely that a *C. perfringens* also accounts for at least some of the foodborne outbreaks for which an etiology is not found.

Sporadic *C. perfringens* food poisoning is even less likely to be recognized, since definitive diagnosis in this setting is very difficult. Further developments in enterotoxin detection assays are likely to change this.

7.3.2. Epidemic Behavior and Contagiousness. Epidemics of *C. perfringens* are usually characterized by high attack rates (usually >50%) with a large number of affected individuals; there were 62 cases per outbreak for the years 1990–2002 (see Table 4). There is no risk of secondary transmission.

The incubation period in most outbreaks varies between 8 and 14 h (median 12 h), but can be as short as 6 h or as long as 24 h.

7.3.3. Geographic, Age, Gender, Racial, and Occupational Distribution. Since the organism is widespread in nature, there is no geographic clustering associated with this organism. Outbreaks have been recorded worldwide. No age, gender, racial, or occupational predilections are known.

7.3.4. Temporal Distribution. It has been stated for many years that outbreaks of *C. perfringens* are more common in the spring and fall in contrast to most other foodborne pathogens, which peak during the summer. However, no such trend has been noted in the United States.

7.3.5. Occurrence in Different Settings. Outbreaks due to this organism are most frequently reported from institutions or large gatherings. The pathogenesis of infection

requires that a meat or fish dish be precooked, slow-cooled, and then reheated to be served. The association with large gatherings may be due to the practice of preparing food in advance for such events or may be simply a reporting artifact, since only such groups may recognize the outbreak as food poisoning.

7.3.6. Nutritional Factors. Proteinaceous meats such as beef, turkey, and chicken are the most frequent vehicles of infection with *C. perfringens*; other foods implicated include other animal and vegetable protein sources such as gravy, stew, minestrone soup, bean burritos, rice pudding, and fried fish paste. *C. perfringens* is common in many foods: It can be recovered from 30 to 80% of raw or frozen meat and poultry,[140] though most strains found in food are nonenterotoxigenic.[141] Cured meats are rarely vehicles in outbreaks as the growth of *C. perfringens* is sensitive to high salt mediums.

7.4. Mechanisms and Routes of Transmission

Most outbreaks involve meat-based meals that have been precooked in bulk, allowed to cool for several hours, and then inadequately reheated. The initial cooking is generally sufficient to kill the vegetative organisms but not the spores, which germinate when the temperature falls below 50°C. Unless this food is reheated to a temperature greater than 75°C, it will contain many viable organisms.[142] In most outbreaks of *C. perfringens* food poisoning, the original source of the bacteria has been assumed to be the food itself.

7.5. Pathogenesis and Immunity

7.5.1. Pathogenesis. Symptoms in *C. perfringens* food poisoning are caused by in vivo production rather than by ingestion of preformed enterotoxin.[108,109,141] In volunteer experiments, this toxin is capable of producing the symptoms of food poisoning, but only when given in much higher amounts than found in epidemiologically linked foods. In fact, by the time enough enterotoxin has accumulated in food to be detectable, the food is generally unpalatable.[143] The fact that the toxin is produced by the bacteria in the intestines accounts for a longer incubation period than that seen in illness such as *S. aureus* food poisoning, which is due to preformed toxin.

Relatively large numbers of organisms are required to produce illness. An early study showed that ingestion of 10^8 organisms was capable of producing illness in 50% of volunteers.[144] Others have estimated that five times that number may be necessary.

Once ingested, the organism proliferates in the intestine, sporulates, and produces its enterotoxin. The toxin binds to a receptor on the brush border of the intestine and inserts into the membrane where it remains attached to the external membrane surface.[145–147] By doing this, the toxin increases permeability of the membrane to ions which leads to salt and water secretion into the lumen and increased intestinal motility.[148] In addition, the clostridial toxin inhibits glucose transport, damages the intestinal epithelium, and causes protein loss into the intestinal lumen. These effects are most prominent in the terminal ileum.[149,150] *C. perfringens* enterotoxin has also been shown to act as a superantigen, stimulating proliferation of T cells.[151]

7.5.2. Immunity. Immunity is not well understood. In one study, 65% of Americans and 84% of Brazilians had antienterotoxin activity in serum.[152] The significance of this finding is unknown. No outbreaks have been studied by these methods in which blood was available prior to the outbreaks so that antienterotoxin immunity could be assessed. In animal studies, enterotoxin antiserum can block the action of the toxin on ligated rabbit loops. It has been suggested, however, that the presence of antibody in serum has little or no effect on toxin activity in the intestine.[153,154]

7.6. Patterns of Host Response

7.6.1. Clinical Features. *C. perfringens* food poisoning is characterized by watery diarrhea and severe, crampy abdominal pain, usually without vomiting, beginning 8–24 h after the incriminated meal. Fever, chills, headache, or other signs of infection usually are not present.

The illness is of short duration, 24 h or less. Rare fatalities have been recorded in debilitated or hospitalized patients who are victims of clostridial food poisoning.

7.6.2. Diagnosis. The diagnosis of *C. perfringens* food poisoning should be considered in any diarrheal illness characterized by abdominal pain and moderate to severe diarrhea, *unaccompanied* by fever or chills. There are usually many other individuals involved in the outbreak, and the suspect food is beef or chicken that has been stewed, roasted, or boiled earlier and then allowed to sit without proper refrigeration. Diagnosis should be made based on detection of 10^5 *C. perfringens*/g in the food sample, and detection of at least 10^6 *C. perfringens* spores/g of fecal material.[155]

B. cereus food poisoning can have a very similar presentation and can be ruled out only by bacteriological study. Enterotoxigenic *E. coli* can also present in this fashion (see Chapter 15), although low-grade fever may be present.

Cholera has more profuse diarrhea, which helps differentiate it from clostridial intoxication. *Salmonella* infection has a longer incubation period and is sometimes accompanied by fever (Chapter 32). CDC criteria for confirmation of an outbreak of *C. perfringens* food poisoning are shown in Table 3. It should be noted when testing implicated foods that numbers of viable clostridia decline rapidly in refrigerated samples.

Several subtyping methods are of use in epidemiological studies. Serotyping has proven useful in the United Kingdom but has been less successful in the United States, where many strains are untypeable with existing reagents. Pulsed-field gel electrophoresis methods have also proven useful for molecular subtyping of *C. perfringens* isolates.[133] It is often advised to test more than one isolate from a fecal sample, since carriage of *C. perfringens* in the human gastrointestinal tract is normal. Bacteriocin typing,[156] plasmid typing,[157] and ribotyping[118,158] have also been successfully applied to the investigations of *C. perfringens* outbreaks.

7.7. Enteritis Necroticans

Enteritis necroticans deserves to be considered separately from type A food poisoning because of its unique clinical features, epidemiology, and pathobiology. This illness is a much more severe, necrotizing disease of the small intestine with a high mortality. The incubation period is 24 h, after which illness ensues with intense abdominal pain, bloody diarrhea, vomiting, and shock. The mortality rate is about 40% and is usually due to intestinal perforation.

In postwar Germany, where the illness was known as Darmbrand ("burnt intestine" or "fire belly"), illness was linked to the consumption of underprocessed canned meat that contained *C. perfringens* type C spores. Women were disproportionately affected, particularly those aged 30–60 years. In 1947, the incidence was 11 in 100,000 and cases peaked in the summer.[102]

In Papua New Guinea, outbreaks of "pig-bel" have been clearly related to the consumption of pork during prolonged feasts. During such feasts, the pig is often improperly cooked, and large quantities of pork are consumed over 3 or 4 days. There is a clear male preponderance of cases, with attack rates being highest in boys less than 10 years of age. The incidence of pig-bel was as high as 500 in 100,000 on the island prior to the introduction of the β-toxoid vaccine (see below).[159]

Sporadic cases of enteritis necroticans have been described in several other countries, particularly in the developing world.[160] An outbreak of this illness occurred in a Khmer refugee camp in Thailand between 1985 and 1986; the incidence reached 440 in 100,000 in the 0- to 10-year-old age group, with a case-fatality rate of 58%.[160]

The organism that causes enteritis necroticans is typically *C. perfringens* type C, which does not generally produce enterotoxin. β-toxin is implicated in this disease. This toxin is a 48 kD protein that is extremely sensitive to proteases. It produces hemorrhagic necrosis of the small intestine, especially at the level of the jejunum. But ingestion of β-toxin-producing bacteria is not sufficient in itself to produce enteritis necroticans. At least three other factors play a role in the pathogenesis of this disease: a low-protein diet, the presence of protease inhibitors, and reduced gastric activity. All of these factors have the effect of decreasing the amount of trypsin in the intestine, and thereby permitting the toxin to act on the intestinal wall.[161,162]

Thus, in postwar Germany, epidemic malnutrition was an important enabling factor. In Papua New Guinea, the usual low-protein diet coupled with trypsin inhibitors in sweet potatoes (commonly eaten during pig feasts) or secreted by ascaris (present in 70–80% of the highland population) have been identified as factors in the pathogenesis of pig-bel.[103]

Antibodies to β-toxin are protective against enteritis necroticans. These antibodies, which are largely absent in European adults and Papuan children, are highly prevalent in Papuan adults; these antibodies may account for the lower incidence of pig-bel in the adult population of the island. A β-toxoid vaccine has been developed and is protective against this disease. The incidence of pig-bel in Papua New Guinea has declined dramatically since the introduction of this vaccine in the early 1980s.[103] More recent cases of necrotizing enterocolitis in previously healthy adults have suggested that *C. perfringens* type A may also cause this disease.[163,164]

8. "Noncholera" *Vibrio* Species

8.1. Historical Background

In the 1930s, cholera researchers realized that *Vibrio cholerae* isolates could be divided into two groups: those that agglutinated with serum from cholera patients (0 group 1) and those that failed to agglutinate. This latter group consisted primarily of environmental isolates that were thought to be nonpathogenic, although there was early speculation that some of these "nonagglutinating" or "noncholera" vibrios might be responsible for such syndromes as "paracholera." Firm evidence of the pathogenicity of these

strains did not emerge until two decades later when the first outbreaks due to these organisms were identified and investigated. As these data accumulated, it became increasingly clear that many of the strains were so distinct from *V. cholerae* as to constitute separate species.[165]

Within the species *V. cholerae*, there are over 150 O groups, only two of which cause epidemic cholera: *V. cholerae* O1 and *V. cholerae* O139. Serotype O1 held a monopoly on this disease until 1992, when O139 emerged and rapidly spread in Asia (see Chapter 12). Other serotypes of *V. cholerae* ("nonepidemic" *V. cholera*) are different in that they generally cause only sporadic illness, rather than large-scale epidemics such as those for which O1 and O139 are infamous.

V. parahaemolyticus was the first noncholera *Vibrio* species to be recognized as an agent of foodborne illness. Fujino and coworkers[166] first isolated this organism from autopsy materials collected during an investigation of a food-poisoning outbreak. Over the subsequent decade, many other outbreaks in Japan incriminated a halophilic, hemolytic gram-negative organism similar to that described by Fujino. The vehicles in these outbreaks were usually raw fish, shellfish, and cucumbers in brine. The names *Pasteurella parahaemolytica, Pseudomonas enteritis*, and *Oceanomonas parahaemolytica* were all suggested before taxonomic studies firmly placed the organism within the genus *Vibrio*.

In addition to *V. parahaemolyticus*, several other *Vibrio* species are known to be enteropathogenic (see Table 6).

Table 6. Clinical Syndromes Due to *Vibrio* Species[a]

	Clinical presentation[b]		
	Gastroenteritis	Wound/ear infection	Primary septicemia
V. cholerae			
O1, O139	++	(+)	
Nonepidemic	++	+	+
V. mimicus	++	+	
V. parahaemolyticus	++	+	(+)
V. fluvialis	++	+	
V. furnissii	++		
V. hollisae	++	+	(+)
V. vulnificus	+	++	++
V. alginolyticus		++	
V. damsela		++	
V. cincinnatiensis			(+)
V. carchariae		(+)	
V. metschnikovii	(+)		(+)

[a] Adopted from Morris.[187]
[b] ++, denotes the most common presentation; +, other clinical presentations; and (+) very rare presentations.

V. fluvialis, V. furnissii, V. hollisae, and *V. minicus* have been well described as agents of sporadic gastroenteritis or of foodborne outbreaks. *V. vulnificus* can cause a syndrome of "primary septicemia" (septicemia without any other obvious source) associated with ingestion of the organism in shellfish. A Gulf Coast Vibrio Surveillance summary from 1988 to 1996 found that a majority of reported vulnificus infections were wound infections (45%) and primary septicemia (43%).[167] Numerous other noncholera *Vibrio* species (there are over 5 dozen known *Vibrio* species) have been described but are not known to be pathogenic.[168]

8.2. Microbiology

8.2.1. Biological Characteristics of the Organisms. Vibrios are ubiquitous of microbes in aquatic environments. They are most common in marine and estuarine environments, though some species such as *V. cholerae* have been isolated from fresh water. In temperate climates, their numbers vary seasonally: In the summer they can easily be isolated from water, suspended particulate matter, plankton, algae, sediment, fish, and shellfish; during the winter months, they decline markedly in number and are found primarily in sediments.[169,170] Nonepidemic *V. cholerae* has been isolated from the Chesapeake Bay, with greater detection in areas above 19°C and salinities between 2 and 14 ppt. Furthermore, modeling methods demonstrate that temperature and salinity conditions can predict the presence of *V. cholerae* with an accuracy of 75.5–88.5%.[171] Other studies in the Chesapeake Bay area have shown that *V. vulnificus* constituted 12% of the total aerobic bacterial flora present in bay water, with peak counts in the range of 10^1–10^3/ml. Counts may be two orders of magnitude higher in filter-feeding mollusks, such as oysters. Virtually 100% of raw oysters harvested during warmer, summer months carry *V. vulnificus*. Studies conducted by the FDA have identified nonepidemic *V. cholerae*, in 14% of oyster shell stock sampled.[172] Environmental isolation rates of 9.6–12.8% have been reported for *V. parahaemolyticus* in the United States.[173]

All *Vibrio* species are facultatively anaerobic, asporogenous, pleomorphic gram-negative rods. Most are highly motile with a single, polar flagellum and are oxidase positive on standard biochemical panels. One consequence of their marine habitat is that most vibrios are "halophilic," requiring salt (at least 1% NaCl) for growth; some will grow in salt concentrations as high as 12%. *V. cholerae* and *V. mimicus* are notable exceptions: Although they grow well in 1% NaCl and can tolerate salt concentrations as high as 6%, they are also able to grow in the absence of salt.

8.2.2. Laboratory Diagnosis. *Vibrio* species will grow on or in most nonselective culture media, including blood agar and commercially available blood culture media. For isolation from stool, use of a selective medium, thiosulfate, citrate, bile salts, and sucrose (TCBS agar), is generally necessary.[169,174] With the exception of some strains of *V. hollisae*, all pathogenic vibrios will grow on this medium, producing colonies that are yellow (sucrose fermenters such as *V. cholerae*) or blue-green (nonsucrose fermenters such as *V. parahaemolyticus* and most *V. vulnificus*). Because the routine use of TCBS is not considered cost-effective in the United States, its use must be specifically requested. Those labs that do not use TCBS typically screen nonselective blood plates for oxidase activity. Susceptibility to vibriostatic agent, O/129, is useful in differentiating most vibrios from other gram-negative bacteria, however, this is not always the case. Some isolates have shown resistance to O/129.[175]

Confirmation of the genus and identification of the species can be accomplished using conventional tests. Because many vibrios are halophilic, the addition of 1% NaCl to growth media is often necessary to prevent false-negative reactions. When examining environmental samples, especially water samples, concentration procedures or selective enrichment broths may be needed.[174] Direct identification from food and water samples may be facilitated by the use of specific DNA probes, PCR, and PFGE profile techniques.[176,177] In recent years, chromogenic mediums and commercial biochemical test kits have been developed to differentiate *vibrio* species.

8.3. Descriptive Epidemiology

8.3.1. Prevalence and Incidence. Because TCBS media is not routinely used by most medical microbiology laboratories, *Vibrio* infections are probably underdiagnosed in the United States. According to a FoodNet lab survey only 50% of on-site labs routinely tested for vibrio and only 27% of those labs used TCBS agar.[178] FoodNet along with the CDC Vibrio Surveillance system, started in 1988, have provided the most comprehensive data to date on the epidemiology of *Vibrio* infections in North America (see Table 7). Among 2003 FoodNet sites, the incidence of *Vibrio* spp. infections varied from 0.1 to 0.6 per 100,000 and was usually highest in coastal states, especially California and Maryland (Table 5). According to a 1996–2002 FoodNet *Vibrio* surveillance summary, *V. parahaemolyticus* was the most common laboratory-confirmed etiology (13%) followed by *V. vulnificus* and *V. cholerae* (both 8%). *V. fluvialis, V. alginolyticus*, and other vibrio species were identified less often (≤6%).[179] A global increase in *Vibrio* infections over the past 10 years is thought to be the result of many factors including an increase in the consumption of raw and lightly cooked seafood, global warming, and the emergence of more virulent vibrio serotypes.

8.3.2. Epidemic Behavior and Contagiousness. Nonepidemic *V. cholerae*, unlike *V. cholerae* O1 and O139, usually causes only sporadic illness rather than widespread epidemics. *V. parahaemolyticus*, on the other hand, frequently occurs in outbreaks. In Japan, where consumption

[b] Data are numbers; percentages are given in parentheses.
[c] Includes ear, gall bladder, peritoneal fluid, sputum, urine, and unknown source.

of raw seafood is relatively common, this organism accounts for 25–60% of all foodborne outbreaks. In the United States, where foodborne outbreaks are usually attributed to raw oyster consumption or the mishandling of seafood, 40 outbreaks involving 920 cases occurred from 1990 to 2002 (see Table 4). Secondary cases after outbreaks of *V. parahaemolyticus* appear to be uncommon. In 1996, a unique serotype O3:K6 was discovered in India and attributed to an increase in *V. parahaemolyticus* infections in that area.[180] Over the past 13 years O3:K6 has emerged as the dominant pandemic serotype in *V. parahaemolyticus* infections worldwide, spreading to other areas of Asia, Chile, the United States, Europe, and Africa. Subsequently this clone has diversified into other serotypes, O1:KUT, O4:K68, and O1:K25. These derivatives represent 28% of *V. parahaemolyticus* serotypes with pandemic potential.[181] Multi-locus sequence typing (MLST) data has provided evidence that post 1995 pandemic strains are clonally derived from serotype O3:K6 and that strains within this group may acquire other serotypes.[182]

Gastrointestinal infections with other *Vibrio* species have a much lower incidence, generally occurring as sporadic cases.[183] One large-scale outbreak of *V. fluvialis* occurred in India in 1981.[184] *V. vulnificus* incidence in the general population is low (0.6 per million) even though it accounts for 95% of seafood consumption-related deaths.[185]

The incubation period for nonepidemic *V. cholerae* in the few documented outbreaks has been from 12 h to 5 days.[186] After experimental infection with one strain of this bacterium, volunteers developed gastroenteritis in a median of 10 h (range, 5.5–96 h). The incubation period for *V. parahaemolyticus* is similar, varying from 4 to 30 h, with most illness occurring 12–24 h after exposure.

8.3.3. Geographic and Temporal Distribution. As noted above, vibrios are common environmental isolates throughout the world; however, strain isolation can vary from region to region. For instance, nonepidemic strains of *V. cholerae* are more commonly isolated from Gulf Coast regions of the United States than epidemic *V. cholerae.*[187] Patterns of illness vary as well. In Taiwan, *V. parahaemolyticus* accounted for approximately 86% of all foodborne outbreaks between 1995 and 2001.[188] Dietary habits (i.e., the consumption of raw seafood) undoubtedly play a role here. In the United States, where *Vibrio* infections are much less common, outbreaks and sporadic cases are concentrated along the Atlantic, Gulf, and Pacific coastlines. Raw oyster consumption is the most common risk factor.[167,189] In developing countries, where *Vibrio* infections are more likely to go undetected, seafood consumption is less commonly implicated as a risk factor for infection. In Cancun, Mexico, where a 2-month survey found nonepidemic *V. cholerae* in 16% of 134 stool samples obtained from persons with diarrhea, home-prepared gelatin was the only statistically significant risk factor in a case–control study.[190] Environmental investigation suggested other possible sources of infection: The organism was obtained from 86% of untreated well water samples, 92% of sewage samples, and 21% of seafood samples. A waterborne outbreak of nonepidemic *V. cholerae* occurred in Sudan in 1968, due to contamination of surface water next to a well.[191]

The incidence of noncholera *Vibrio* infections varies with season, being highest in the summer and fall. This is most likely a consequence of the higher number of vibrios in aquatic environments as well as in fish and shellfish harvested during these months.

According to the World Health Organization (WHO), the risk of *Vibrio* transmission with imported foods from endemic areas is very small. Commercial imports have not been implicated in any known *Vibrio* outbreaks. WHO recommends that importing countries agree with food exporters, to enforce good hygienic practices during food handling and processing to prevent, eliminate, or minimize the risk of any potential contamination.[192]

8.3.4. Age, Gender, Race, and Other Host Factors. Host factors such as race appear to play little role in the acquisition of gastroenteritis from *Vibrio* species. Factors such as gender or age do appear to correlate with disease. The median age of persons diagnosed with *Vibrio* gastroenteritis varies with geographic location: In Cancun, Mexico, for example, children less than 1 year of age were at highest risk, whereas in Bangladesh and Thailand cases have tended to occur in older children and adults.[190,193,194] Surveys of sporadic *V. parahaemolyticus* and *V. vulnificus* infections in the United States found a median age of 36 years (V.p.) and 35 years (V.v.) for gastroenteritis and 46 years (V.p.) and 54 years (V.v.) for septicemia.[167,195] These findings may reflect the older age of the population that consumes raw oysters. An estimated one in ten Americans occasionally eat raw shellfish[195,196] and have pre-existing medical conditions which lead to cases of sepsis. *Vibrio* also appears to be more prevalent in males than in females. A 2003 CDC *Vibrio* FoodNet survey reported that *Vibrio* incidence was 52% higher in males than females.[197] While this difference might be a reflection of gender-related food preferences, it may also be the result of an estrogen-driving mechanism.[198]

Host factors play a major role in the epidemiology of sepsis due to *Vibrio* species. Most patients with sepsis due to *V. vulnificus* and nonepidemic *V. cholerae*, for example, have an underlying chronic medical illness. Those with liver disease, such as alcoholic cirrhosis or hemochromatosis, are especially at risk. Although it has never been shown con-

clusively that sepsis infections are acquired through the gastrointestinal tract, their strong association with raw oyster consumption has always been cited as evidence to support this assertion.[165]

8.4. Mechanisms and Routes of Transmission

Foodborne transmission has been by far the most important route of transmission of noncholera vibrios in studies of epidemic and sporadic illness. As noted above, waterborne outbreaks have occurred, but are rare and are limited to the developing world. Person-to-person transmission may occur, but evidence for this is scant.

In the United States and Japan, noncholera *Vibrio* gastroenteritis is acquired almost exclusively via the foodborne route. Seafood, especially raw seafood, is the most common vehicle implicated in outbreaks and in sporadic disease. A *Vibrio* Working Group study found that 83% of patients with gastroenteritis and 96% of patients with primary septicemia had ingested raw oysters during the week prior to their illness.[167] A summary of *V. parahaemolyticus* infections in the United States between 1988 and 1997, found that 88% of those with gastroenteritis reported eating raw oysters before illness.[195] Other seafood such as crayfish,[199] clams, crabs, and shrimp have been implicated in outbreaks in the United States. In Japan, most outbreaks of *V. parahaemolyticus* have been due to saltwater fish or foods contaminated by seawater.[200]

Food-handling practices frequently play a role in outbreaks of noncholera vibrios. Seafood naturally contaminated with vibrios and held at an improper temperature can become heavily contaminated. *V. parahaemolyticus*, for example, has a generation time of 12 min under optimal circumstances and can increase its numbers by 1,000-fold in 2 h.[201] Likewise, already contaminated seafood may be cooked to an inadequate time–temperature combination sufficient to kill the organism. Finally, even uncontaminated or properly cooked seafood may be washed with contaminated salt water after preparation. The latter mechanism has been described in several outbreaks of *V. parahaemolyticus* abroad cruise ships.[202]

Because secondary transmission after outbreaks of noncholera vibrios is unusual, person-to-person transmission is thought not to be important in the epidemiology of these organisms. Long-term carriage has not been documented, though asymptomatic infections may be relatively common. From a cohort of 479 physicians attending a meeting in New Orleans who agreed to submit stool samples, 51 stool samples were positive for noncholera vibrios (*V. parahaemolyticus*, nonepidemic *V. cholerae, V. vulnificus, V. fluvialis*, and *V. mimicus*), of which 36 had been collected from individuals reporting no recent diarrheal illness.[203] In a large study conducted in Iran in 1971, 1.6% of pilgrims returning from Mecca were estimated to be carriers of nonepidemic *V. cholerae* (compared with 0.02% of persons leaving for Mecca). Isolations of this organism from stool cultures obtained from the contacts of these pilgrims increased over the following 6 months and decreased thereafter. Of these contacts, 60% reported diarrheal illness.[204]

8.5. Pathogenesis and Immunity

8.5.1. Pathogenesis

8.5.1.1. Nonepidemic V. cholerae. Given the relatively low incidence of this infection and the relatively high prevalence of these organisms in foods such as oysters, it is likely that virulence factors play a role in the epidemiology of these infections. Three enterotoxins—cholera toxin (CT), NAG-ST, and E1 Tor hemolysin—have been described. The 85 kD heat-labile cholera toxin is thought to bind to specific receptors in the lumen, resulting in massive loss of liquid in the intestine; additional secretory mechanisms are unclear. CT-producing species have been isolated most commonly in the Indian subcontinent and are associated with more severe nonepidemic *V. cholerae* disease.[205] However, these CT-producing strains represent only a small proportion of nonepidemic *V. cholerae* cases.[206,207] Non-agglutinable *Vibrio cholerae* heat-stable enterotoxin (NAG-ST) is similar to heat-stable enterotoxins found in *V. parahaemolyticus*, *E. coli*, and *Yersinia enterocolitica*. Its proposed mechanism is stimulation of nitric oxide production in intestinal cells.[208] A NAG-ST-producing strain has been demonstrated to cause diarrhea in young, previously healthy volunteers, whereas an otherwise similar but NAG-ST-negative strain was unable to do so despite being able to colonize the gastrointestinal tract.[209] As with CT-producing strains, NAG-ST-positive strains account for only a small portion of all clinical nonepidemic *V. cholerae* isolates.[210,211] E1 Tor hemolysin (aka *V. cholerae* cytolysin (VCC) or HlyA), on the other hand, is present in all nonepidemic *V. cholerae* strains and is responsible for the hemolytic activity of this species. More recently a novel hemolysin has been identified in a *V. cholerae* strain, although it is thought to not contribute to pathogenicity.[212] El Tor hemolysin has demonstrable enterotoxic activity causing vacuolation and death of cultured cells[213–215] and may be responsible for the enterotoxic activity of CT-negative strains. Homologous hemolysins with enterotoxin properties have also been identified in other *Vibrio* species.[216–219] However, E1 Tor hemolysin alone is not sufficient to produce illness.

Strains producing this hemolysin that are able to colonize the intestine do not necessarily produce diarrhea.[209] Also, mice given intranasal administration of *V. cholerae* containing deletions within hemolysin genes still experienced acute inflammatory responses.[220] Zonal occludens toxin and accessory cholera toxin genes as well as Shiga-like toxin and various other hemagglutinins and hemolysins (whose contribution to pathogenicity have not been resolved) have also been found in non-O1/O139 strains.[221] The production of a polysaccharide capsule has been found in over 90% of nonepidemic *V. cholerae* strains; heavier encapsulation has a strong association with septicemia.[187] The capsule confers resistance to serum bactericidal activity.[222]

8.5.1.2. V. parahaemolyticus. The most important virulence factor to date is the thermostable direct hemolysin (V_p-TDH), which is responsible for the β-hemolysis seen when these isolates are plated on Wagatsuma agar. Original studies in Japan showed that this phenomenon, named the Kanagawa phenomenon after the prefecture in Japan where it was discovered, was noted in 96% of clinical isolates but only 1% of environmental isolates.[200] It has been found that one-point mutation in the promoter of *tdh* genes in Kanagawa-negative clones can generate a Kanagawa-positive subclone.[353] This result may give insight into disparities in the Kanagawa reaction found in clinical vs. environmental isolates. Volunteer studies also demonstrated the importance of Vp-TDH: Kanagawa-positive strains produced diarrhea, whereas doses of up to 10^9 Kanagawa-negative strains failed to do so in 15 volunteers.[222] Furthermore, studies with isogenic mutants have shown that deletion of the Vp-TDH gene results in loss of enterotoxic activity in laboratory models (using chamber and rabbit ileal loop assays).[223] Kanagawa-negative isolates produce another group of important virulence factors, hemolysins known as V_p-TDH related hemolysins or V_p-TRH. These hemolysins are genetically related to V_p-TDH (they share around 70% sequence homology) but are more diverse (<2.8% divergence among most V_p-TDH vs. 16% between two subgroups of V_p-TRH).[224] Also present is a third hemolysin, thermolabile hemolysin (TLH), also called the lecithin-dependent hemolysin (LDH). The role of LDH in pathogenicity has not been elucidated. Urease production is also linked to virulence. The urease gene cluster lies in close proximity to the V_p-TRH gene on the *V. parahaemolyticus*chromosome, but does not influence the expression of this gene (or V_p-TDH).[225,226] Urease-positive strains that are Kanagawa-negative and lack V_p-TDH and V_p-TRH genes have shown enteropathic activity in a ligated rabbit ileal loop model.[227] Other virulence factors reported over the years include an enterotoxin, a cytotoxic shigatoxin, and various enzymes and adhesins.[228]

V. parahaemolyticus can cause a dysentery-like syndrome, indicating that they may also produce illness by invasion of the intestinal wall. Limited animal studies support this assertion; however, invasion has been demonstrated in vitro and a functional type III secretion system has been characterized.[229–232]

8.5.2. Immunity. Multiple serotypes of *V. parahaemolyticus* can be isolated from a patient's stools, and frequently more than one strain is isolated from an incriminated food.[233] While there has been documented immune response to *V. parahaemolyticus*, it is not known whether infection results in immunity or whether such immunity is serotype- or species-specific.[234] The fortuitous occurrence of two outbreaks of *V. parahaemolyticus* during a single Caribbean cruise demonstrates that it is possible for infection to occur more than once in a given individual within a relatively short period of time (6 days).[202]

8.6. Patterns of Host Response

8.6.1. Nonepidemic *V. cholerae*. Three distinct clinical syndromes—gastroenteritis, wound infections, and primary septicemia—are seen in patients affected by nonepidemic *V. cholerae*.

The severity of gastroenteritis produced by these organisms varies from asymptomatic colonization to heavy, cholera-like purges. In studies of sporadic illness where cases that have been identified retrospectively on the basis of stool cultures, illness has been relatively severe. Among 14 sporadic cases identified in a study in the United States, the median duration of illness was 6.4 days.[196] All of these patients had diarrhea, 71% had fever, but only 21% had nausea and vomiting. One quarter of these patients had bloody diarrhea. In a group of 19 sporadic cases in Bangladesh, the median stool volume was less than 1 l, with a maximum of 8 l; the median duration of illness was less than 24 h, with a maximum of 2.5 days.[235] Experimental infections in normal volunteers and cases identified through outbreak investigations have shown less severe illness, with median durations of 12–24 h and with diarrhea generally lasting less than 4 days.[186]

Septicemia with nonepidemic *V. cholerae* generally occurs in immunocompromised patients, particularly those with liver disease or hematologic malignancies. The case-fatality rate among reported cases has been over 50%. Strains responsible for septicemia have been uniformly found to be heavily encapsulated.

Nonepidemic *V. cholerae* have been isolated from wounds, ears, sputum, urine, and cerebrospinal fluid. In many of these cases, a variety of other potential pathogens

have also been isolated from the same site, making it uncertain that the nonepidemic *V. cholerae* was the true pathogen.[186]

8.6.2. *V. parahaemolyticus.* *V. parahaemolyticus* produces a spectrum of illness very similar to that of nonepidemic *V. cholerae*. Gastroenteritis is the most common syndrome, with diarrhea (98%), abdominal cramps (89%), nausea (76%), and fever (52%).[195] Bloody stools were noted in 29% of *V. parahaemolyticus* gastroenteritis cases between 1973 and 1998,[195] as well as in cases in India and Bangladesh. In both the United States and Japan, illness tends to be mild, with a median duration of 3 days and a very low case-fatality rate. Of the 1,064 *V. parahaemolyticus* illnesses reported in the United States between 1973 and 1998, only one patient died.[195] Outbreaks of severe gastrointestinal illness have been reported. Hypotension and shock occurred in three of five cases in one outbreak in Great Britain,[236] and there were 20 deaths among the 272 patients involved in the Japanese outbreak where *V. parahaemolyticus* was first identified.[237]

V. parahaemolyticus also causes infection in wounds exposed to seawater. Such infections can disseminate and cause sepsis. A surge in wound infections was observed in the aftermath of a severe Gulf Coast hurricane in 2005, Hurricane Katrina, that disrupted sewage systems and displaced thousands of people, some of them wading through contaminated water to get to safety. During the 2 weeks following Hurricane Katrina, 22 new cases of *Vibrio* infections were reported, with 82% of those being wound infections; of the wound infections, 18% were caused by *V. parahaemolyticus* (82% were caused by *V. vulnificus*).[238] Primary septicemia has also been reported, but is not seen as commonly as with *V. vulnificus* or nonepidemic *V. cholerae*.

8.6.3. Other Pathogenic *Vibrio* Species. *V. fluvialis, V. furnissii, V. hollisae*, and *V. mimicus* all cause gastroenteritis. In a Gulf Coast study, *V. fluvialis* was particularly likely to produce bloody diarrhea (six of seven cases).[189]

The principal clinical manifestations of *V. vulnificus* include primary septicemia and wound infections, with a minority (5%) experiencing only gastroenteritis.[167] One-third of patients with primary septicemia present in shock; 70–90% have characteristic bullous skin lesions. The mortality rate for persons with primary septicemia exceeds 50%. Sixty-one percent of the fatal cases report an underlying chronic liver disease.[167] For patients who present in shock, mortality exceeds 90%. Survivors often have multiple organ system failure, requiring protracted hospitalization and rehabilitation. Wound infections are not caused by consumption of raw shellfish. During Hurricane Katrina, 82% of wound infections were caused by *V. vulnificus.*[238] Lesions are typically present on the extremities, most frequently on the legs. Wound infections range from mild, self-limited infections to severe, rapidly progressive myositis and fasciitis.[165]

9. *Aeromonas* Species

9.1. History

Microbiologists have studied aeromonads for over a century. Sanarelli was the first to observe these organisms, which he had isolated from a frog in 1891 and named *Bacillus hydrophilus.*[239] Although early studies showed that direct inoculation produced septicemia and death in animals, the role of these organisms as human pathogens was not recognized until the 1960s. Interest in aeromonads grew considerably with the first publication in 1968 of a review of 28 cases of human *Aeromonas* infections.[233] Although work since then has confirmed the pathogenicity of these organisms, controversy still remains as to the role of aeromonads in gastroenteritis because there have been a lack of volunteer trials and animal models for this disease. However, there now exists a wealth of epidemiologic support for the role of some *Aeromonas* species in foodborne gastroenteritis. *Aeromonas* has become increasingly important in foodborne illness, now being listed on both the FDA "Bad Bug List"[240] and the EPA "Drinking Water Contaminant Candidate List".[241]

9.2. Microbiology

9.2.1. Biological Characteristics of the Organism. Aeromonads are facultatively anaerobic, gram-negative rods with single polar flagella. Species that are pathogenic in humans are oxidase-positive, catalase-positive, and reduce nitrate to nitrite. All ferment D-glucose and most will produce gas in doing so (hence their name). *Aeromonas* species can be divided into two groups: mesophiles, which grow well in a wide variety of temperatures (10–42°C), and psychrophiles, which grow best at lower temperatures (less than 35–37°C). Species in this latter group are not pathogenic in humans but can cause disease in cold-blooded vertebrates and fish.[242]

The taxonomy of the *Aeromonas* genus, which until the mid-1970s was thought to consist of three species, has become complex, with more than 17 phenotypic species now known to exist.[1,242,243] The application of DNA hybridization techniques has led to the division of some phenotypic species (such as *A. sobria*) into more separate genospecies (*A. veronii, A. jandaei*, and *A. schubertii*, in this case).[244] Of *Aeromonas* species, three—*A. hydrophila, A. caviae*, and *A. veronii* biotype sobria—account for more than 85%

of all clinical isolates from humans. Another three—*A. jandaei, A. schubertii*, and *A. veronii*biovar veronii—are considered minor human pathogens. Because of their phenotypic similarities, the genera *Aeromonas* and *Vibrio* were originally placed into a single family (Vibrionaceae) along with one other genus, *Plesiomonas*. However, increasing genetic evidence suggested that *Aeromonas* was so distinct from genera in other families including Vibrionaceae or Enterobacteriaceae that it should constitute its own family.[245] Therefore, in the 2nd edition of *Bergey's Manual of Systematic Bacteriology-Vol. 2*, *Aeromonas* spp. forms the Aeromonadacae family.[1]

The ecology of aeromonads is similar to that of *Vibrio* species. They are autochthonous (free-living) organisms that can be isolated from freshwater, brackish water, occasionally from seawater, and also from the fish, fish eggs, and shellfish that inhabit these environments. However, their isolation from cold-blooded animals, soil, tree bark,[246] ticks,[247] and various other foodstuffs demonstrate that they are not just found in aquatic environments. Their numbers vary seasonally, being highest during the warmer months of May through November. Most foodborne outbreaks are associated with mesophilic species, which can grow at refrigeration temperatures with an optimal growth temperature of 28°C.[248]

9.2.2. Laboratory Diagnosis. *Aeromonas* species are hardy organisms and will grow on a large variety of media, though they may be overlooked on certain semiselective media such as Hektoen enteric or MacConkey agars because some are sucrose-positive (most *Aeromonas* species) or lactose-positive (*A. caviae*). Blood agar has the advantage of allowing easy testing of colonies for oxidase and indole production and also permits the identification of hemolytic species (*A. hydrophila* and *A. veronii*).[249] The addition of ampicillin makes this medium more specific, but excludes *Aeromonas* species that are ampicillin-susceptible (including all *A. trota* and 15–57% *A. caviae* isolates). Modified cefsulodin–irgasan–novobiocin (CIN) agar, which is commonly used for *Y. enterocolitica*, has also been shown to be useful for *Aeromonas.*[250] Both ABA and CIN media are recommended for optimal isolation.[249] A European study looked at *Aeromonas*isolation on xylose–galactosidase medium (XGM).[251] Aeromonas was isolated more frequently on XGM agar (36%) than from any other medium except CIN (43%), but XGM had fewer false positives (11% for XGM vs. 60% for CIN). Enrichment on alkaline peptone water (pH 8.5) (also used for *Vibrio* species) is useful for stools obtained after the acute phase of the illness, when numbers of viable organisms have usually dropped considerably. Gram-negative and Selenite–F broths used for enrichment of *Salmonella* and *Shigella* can also be used for aeromonad recovery.[242] Symptoms of *Aeromonas* sp. infection range from mild gastroenteritis to wound infections. Therefore, the decision to do species or broad complex-level identification (*A. hydrophila*, *A. caviae*, or *A. veronii*) of aeromonads depends on the clinical outcome of the cases from which they were isolated, and because the identification of aeromonads in fecal specimens may not be involved with diarrheal disease (see below), the relative quantity of recovered isolates should be reported as well.[252]

One recurring problem is that *Aeromonas* isolates are frequently mistaken for halophilic vibrios. *Aeromonas* can be differentiated from vibrios using preparations containing 6% NaCl in which *Aeromonas* cannot grow. *Aeromonas* is also resistant to 150 μg vibriostatic agent (O/129).[248] Nevertheless, there are exceptions to these rules. Serotyping and additional testing are recommended to differentiate *A. veronii*biovar veronii from *V. cholerae.*[252] *A. caviae* is particularly difficult to separate from *V. hollisae*; additional salt tolerance and esculin hydrolysis tests are needed.

Phenotypic species identification can be difficult in the case of *Aeromonas*: most commercially available kits are inadequate for this.[248,253] In outbreak investigations or for unusual clinical cases, genospecies identification should be attempted.[254] Several molecular techniques have been used in genotyping. PCR of cytolytic and cytotonic genes is used in some laboratories.[255,256] RFLP and PFGE of housekeeping genes are also used.[257] Serotyping may also be useful in epidemiologic investigations.[258,259]

9.3. Descriptive Epidemiology

Aeromonas species has become increasingly recognized as a common cause of enteric infections. *Aeromonas* species are frequently isolated from stools of patients with diarrhea and, in some studies, have been the most frequently isolated potential pathogen.[239,260] One epidemiologic study found that *Aeromonas* was the only pathogen isolated in diarrheic infants.[261] International studies have indicated the incidence of *Aeromonas* in children at 2.3% in Taiwan 2.8% in Switzerland and as much as 13% in Nigeria and 50% in Peru.[262–265] In an even more recent Iranian case–control study, 3.9% of pediatric diarrheal patients were found to harbor *Aeromonas* spp. as the sole pathogen in stool cultures, but no *Aeromonas* was isolated from controls.[266] Rates tend to be lowest in industrialized countries and highest in developing countries indicating that sanitary conditions may be one determining factor in the epidemiology of this infection. In Sweden, *Aeromonas* was found in 2% of adult diarrheal infections, the most common risk factor being travel.[267] *Aeromonas* has been implicated in traveler's diarrhea in a number of other studies as well.[268–270] In the United States, surveys have found isolation rates of 2.5–7.1% in patients

with diarrhea. At least one study indicates that males may be preferentially affected by *Aeromonas* septicemia.[271]

It is worth noting, however, that Aeromonads can be found in up to 8% of asymptomatic individuals; and excretion rates of 0–2% have been recorded in healthy individuals.[272] Furthermore, although some studies have shown that *Aeromonas* is more common in stools of symptomatic patients, several studies have found *Aeromonas* to be equally common in asymptomatic individuals.[260] Other potential pathogens are often found in stools testing positive for *Aeromonas.*[265,273] As of yet, a reliable animal model for *Aeromonas* has not been identified.

Isolation from stool and from extraintestinal sites (predominantly blood and wounds) is more common in the warmer months of the year when aeromonads are present in higher numbers in the environment and contact with water and consumption of *Aeromonas*-carrying foods may be higher.[239,271] The prevalence of *Aeromonas* species varies by geographic location. *A. caviae* has reportedly been the most frequently isolated species in parts of Bangladesh[274] and the United States and Europe.[275] Other studies have shown that *A. sobria* and *A. hydrophilia* are the predominate clinical and environmental isolates in southern India,[273] Australia, Thailand, the Netherlands, and Bangladesh.[275]

In California, where reporting of *Aeromonas* infections has been mandatory since 1988, a 1992 review showed the annual incidence to be 1.1 per 100,000 in all age groups combined and around 5 per 100,000 for children less than 2 years old.[276] The most common site of isolation was the gastrointestinal tract (85%), followed by wounds (9%). *Aeromonas* is also more commonly found in both elderly and immunocompromised individuals.

9.4. Mechanisms and Routes of Transmission

Aeromonas is usually associated with the consumption of cooked prawns, raw fish, or raw oysters.[277–279] For most of these cases, suspected foods are usually prefrozen or improperly stored and then inadequately heated before consumption.[248] *Aeromonas* has also been detected in milk, vegetables, poultry, and meat. Under experimental atmospheric conditions, *Aeromonas* has been shown to grow rapidly in lettuce[280] and can also grow well in milk.[281]

Studies of sporadic *Aeromonas* infections have revealed different risk factors. One study in the United States found consumption of untreated well water to be associated with this infection;[282] a second study found both untreated well water and prior antibiotic therapy to be risk factors.[283] An outbreak in a children's hospital ward in India found equivalent *A. veronii* biotype isolates in a sink; because the outbreak evolved over the course of a month, person-to-person transmission was suspected.[284] Further studies have found that flies harbor[285] and transmit *Aeromonas* from fly-to-fly and fly-to-food.[286]

9.5. Pathogenesis and Immunity

While *Aeromonas* species produce a wide variety of extracellular virulence factors, two categories of extracellular molecules are believed to play a role in the pathogenesis of *Aeromonas*: colonization factors and enterotoxin production. The type IV pilin, Bfp, is thought to promote colonization as it has been shown to mediate adherence to enterocytes.[287] Adhesion properties of *Aeromonas* strains have been found to correlate with production of other virulence factors.[288] It has been reported that only 24% of *Aeromonas* isolates, especially those obtained from clinical specimens, secrete enterotoxins, which are categorized into two general groups: cytolytic and cytotonic.[242,289,290] Of the cytolytic enterotoxins there is a well-characterized pore-forming aerolysin toxin and cytotoxic enterotoxin (Act). Like aerolysin, Act is hemolytic and pore-forming, but it also induces a number of host inflammatory responses and stress factors. Act is lethal when injected into mice intravenously.[291] Although both aerolysin and Act share similar function, they differ in sequence and structure. Two variants of the toxins are believed to exist. One variant constitutes the aerolysin family of 49–55 kD enterotoxins. The other class of enterotoxin is composed of 64–69 kD proteins containing 45–51% sequence homology to the HlyA hemolysin of *V. cholerae*;[292,293] studies have shown that distribution of this hemolysin gene varies by *Aeromonas* species.[294] Thus far, cytotonic enterotoxins have been shown to have different molecular weights and physiologic properties.[291] Both a heat-labile (Alt) and a heat-stabile (Ast) enterotoxin have been well characterized by the Chopra laboratory.[272] They have been shown to induce fluid secretion in rabbit ileal loop assays and increase cAMP and PGE_2 levels in the intestine. Past serological, cell, and animal assay evidence suggested that cytotonic enterotoxin production may occur in only a small fraction (<6%) of environmental isolates,[295,296] but since then new reports using DNA techniques have shown that 75% of food-poisoning outbreak strains in Norway contain the *alt* gene.[256] Pathogenic mechanisms of other types of *Aeromonas* infections are induced by a variety of other hemolysins, adhesins, proteases, and lipases. Type III secretion systems, which inject virulence proteins directly into host cells, and quorum sensing mechanisms, which regulate virulence factor production based on the density of bacteria, may also be important for the colonization and invasion of host cells.[272] Type III secretion systems have

been shown to play a greater role than Act in host cell cytotoxicity during early (2 h) bacterial–host cell interactions, but Act contributes more during the later stages of infection.[297] The hemolytic uremic syndrome caused by *Aeromonas* is likely due to a Shiga toxin, but more studies are required for confirmation of its existence. In general, it has been found that pathogenic strains isolated from diarrheal patients express toxins better than those found in asymptomatic controls.[277,288]

9.6. Patterns of Host Response

There appears to be a correlation between species type and clinical outcome. Species most commonly associated with gastroenterititis are *A. veronii* biovar sobria, *A. hydrophila*, and *A. caviae* and to a lesser extent *A. veronii* biovar veronii, *A. trota*, and *A. jandaei*.[248] Gastroenteritis varies considerably in severity and is usually self-limited.[261,282,298–301] Watery diarrhea, with a median of eight bowel movements per day, is often associated with abdominal pain (60–70%), vomiting (20–40%), fever (20–40%), and nausea (20%).[257] The diarrhea is occasionally so severe that it resembles cholera, with up to 40 stools per day. A minority of patients with *Aeromonas* gastroenteritis will develop a dysenteric syndrome resembling shigellosis, with blood and mucus in the stools. Children with this form of illness often require hospitalization. There have also been descriptions of a third, much less common syndrome of subacute or chronic diarrhea lasting for more than 10 days and up to several years.[302] Work in Bangladesh has shown that loose stools are most often associated with *alt* gene-containing isolates and more severe manifestations were caused by strains that harbored both *alt* and *ast* genes.[303] Reports of successful antibiotic treatment of patients with this syndrome lend support to the notion that *Aeromonas* is a true gastrointestinal pathogen.

Wound infections, the second most common clinical manifestation due to *Aeromonas*, usually (but not invariably) occur after exposure of open wounds to environmental water sources[304–306] and are most frequently associated with *A. schubertii* and *A. veronii* biovar sobria (in cases of medicinal leech use).[248] Cellulitis is the most common pattern but more severe infections can occur in immunocompetent individuals, including myonecrosis with gas formation that is rapidly fatal without aggressive treatment. These types of infections were seen among survivors of the 2004 Asian tsunami.[307] Treatment must be considered carefully, as *Aeromonas* infections tend to mimic staphylococcal or streptococcal soft-tissue infections due to high pathogenicity and resistance to penicillin. *Aeromonas* are not susceptible to empirical antibiotic treatment commonly used in wound infections, however, it has been successfully treated with fluoroquinolones, third-generation cephalosporins, and cotrimoxazoles.[306]

In immunocompromised individuals, especially those with malignancy, hepatobiliary disease, and diabetes, bacteremia has been described as well as other forms of invasive disease such as bacterial peritonitis. Most of those with *Aeromonas*-bacteremia have *A. hydrophila*, *A. veronii* biovar sobria, and *A. jandaei* infections. However, a case of septicemia was reportedly caused by *A. veronii* biovar veronii strain.[308] Other clinical syndromes reported in the literature include osteomyelitis, ocular infections, pelvic infections, and pneumonia.[239,309–311] Hemolytic uremic syndrome and renal complications have been reported as sequelae of *Aeromonas* gastroenteritis,[312–315] as well as relapsing intermittent diarrhea.[252]

10. *Plesiomonas*

10.1. History

Plesiomonas was first described by Ferguson and Henderson[316] in 1947, who noted that the properties of this organism resembled those of *Shigella*. Originally named simply "C27," this species was later placed variously in the genera *Pseudomonas, Fergusonia, Scatamonas, Vibrio*, and *Aeromonas*, until 1962, when it was definitely placed into a genus by itself, *Plesiomonas*.[317] The name is derived from the Greek word for "neighbor" and was chosen because of the close relationship that was thought to exist between this genus and the genus *Aeromonas*. Although the genus *Plesiomonas* originally resided in the Vibrionaceae family, recent phylogenetic data revealing that plesiomonads are more closely related to Enterobacteriaceae resulted in their transfer to this family.

10.2. Microbiology

10.2.1. Biological Characteristics of the Organism. *Plesiomonas*, unlike *Aeromonas*, has just one hybridization group, *P. shigelloides*. Like *Aeromonas*, *P. shigelloides* are also facultative anaerobic, gram-negative rods that are positive for oxidase, catalase, and nitrite reduction. They are highly motile by means of two to five polar flagella. Although they ferment D-glucose, they do not produce gas in doing so. The species name, *shigelloides*, is due to its antigenic similarity to *Shigella* species, especially *S. sonnei*.[318,319] *P. shigelloides* is susceptible to O/129, a vibriostatic agent used to distinguish *Vibrio* spp. from *Aeromonas* spp. and other gram-negative oxidase-positive bacilli. *P. shigelloides* is unable to grow on 6% NaCl.

P. shigelloides is primarily a freshwater organism, though it can also be found in estuaries and can occasionally be isolated from seawater. It can also be recovered from sediments, fish, shellfish, and occasionally in the feces of asymptomatic cold-blooded and warm-blooded animals. Isolation of *P. shigelloides* is highest during warmer months.

10.2.2. Laboratory Diagnosis. Because this species, unlike most enteric organisms, can use inositol as a carbon source,[320] agar containing inositol–brilliant green–bile salts is particularly useful. Isolation media may also contain xylose-sodium deoxycholate-citrate. Selective enrichment in alkaline peptone water is also useful for *Plesiomonas* in certain situations. Despite the large number of similarities between *Plesiomonas* and *Aeromonas*, a barrage of tests can be used to differentiate the two, including exoenzyme production, myoinositol fermentation, and decarboxylation of ornithine.[248] Commercial preparations are also available for rapid detection.[321] Because *P. shigelloides* grows optimally at 38–39°C, low temperatures (42–44°C) can be used for its isolation in samples suspected to contain aeromonads. An international serotyping system is available for epidemiological investigations,[322] which employs over 100 serovars using combinations from 76 O and 41 H antigens.[248]

10.3. Descriptive Epidemiology

There is considerable epidemiological evidence supporting the role of *Plesiomonas* as an enteropathogen.[323–325] Two outbreaks have been identified in which predominant serotypes (O17:H2 in one, O24:H5 in another) have been identified,[323] and an outbreak of gastroenteritis caused by *P. shigelloides* and *Salmonella* was reported by the CDC, in which contaminated water and potato salad were thought to be the vehicles.[324] Plesiomonas has also been reportedly isolated from Chinese soldiers.[326] In further support of the enteropathogenic role of *Plesiomonas*, when asymptomatic controls have been studied, carriage rates have usually been less than 1% (although higher in developing countries). In most reported cases of gastrointestinal disease, *Plesiomonas* has been the predominant organism in the stool. Other pathogens are generally not found when sought. Several case reports have noted clinical improvement and disappearance of *Plesiomonas* from stool cultures after treatment with antibiotics to which *Plesiomonas* is susceptible.[327,328] Virulence of *P. shigelloides* has not been confirmed by experimental studies.

The incidence of *Plesiomonas*-associated diarrhea is largely unknown. In a study of stool specimens submitted to a Canadian reference laboratory, the isolation rate was similar to that of *Aeromonas* (25 out of 17,820 specimens).[324,328] A study in Taiwan reported that one-third of pediatric patients harboring *Plesiomonas* also had other enteric pathogens isolated from stool specimens.[329] Thirty-five percent of the cases occurred in children 2 years of age or younger.[329] Despite this, *Plesiomonas* can affect all age groups. *Plesiomonas* affects all health conditions as well. However, rates of *Plesiomonas* infections in HIV-positive populations of Taiwan have shown an increase;[330] also extraintestinal infections associated with immunocompromised health status (esp. underlying biliary tract or liver disease) are becoming more apparent.[331]

10.4. Mechanisms and Routes of Transmission

Several possible *Plesiomonas*-related outbreaks have been reported, mostly from Japan. The most common vehicles implicated are raw or undercooked fish or shellfish. Chicken and water have also been implicated.

Sporadic *Plesiomonas* gastroenteritis has been linked to both seafood consumption and foreign travel.[324,327,328] In a case–control study of sporadic illness, published by the CDC, both of these factors correlated with infection ($p<0.001$ for both); 21 of the 31 cases had one of both of these risk factors.[327] A 1997 Japanese study revealed that *P. shigelloides* is the third most common cause of traveler's diarrhea in that country.[268]

Like *Aeromonas*, *P. shigelloides* is unlikely to grow in foods with high acidity or salt content (more than 3–3.5% wt/wt).[248]

10.5. Pathogenesis and Immunity

Little is known about virulence factors in *Plesiomonas*. No colonization factors such as pili have yet been described. A β-hemolysin has been found and is reported to be present in more than 90% of isolates.[332] This hemolysin may have enterotoxic activity similar to that of aerolysin and may be important in making iron available to the bacteria. Culture filtrates from aquatic isolates were shown to cause intracellular vacuolation on mammalian cells and produce hemolytic and enterotoxic activities.[333] Also, a complex of three heat-stabile LPS-binding proteins and LPS was column purified from *Plesiomonas* culture filtrates. The protein portion had cytotoxic and enteropathogenic activity.[334] Adhesion and invasion by *P. shigelloides* have been reported.[335] Factors involved in adherence and invasion are unknown.

10.6. Patterns of Host Response

Three general clinical manifestations of enteric *Plesiomonas* infection have been described: (1) Watery diarrhea is the most common form, with abdominal pain and some-

times with vomiting or fever. (2) Some experience a more prolonged subacute diarrhea lasting anywhere from 14 days to 3 months. (3) Frank mucus or blood has also been detected in an invasive form of *P. shigelloides* more similar to colitis.[321,336] Most patients experience severe abdominal pain and cramping; and 25–40% of patients experience fever and/or vomiting.[321] Children in Bangladesh have exhibited watery diarrhea (84%), dysentery (16%), vomiting (71%), and fever (8%), with duration being 2 weeks or longer.[337]

Many forms of extraintestinal infection have been reported. Meningitis is the most common of these and is seen in neonates.[338] Septicemia and bacterial peritonitis have been reported in adults, especially those with cirrhosis or who are otherwise immunocompromised.[338] Septic arthritis, endophthalmitis, and cellulitis have been described.[336]

11. Control and Prevention

11.1. General Concepts

11.1.1. Food Safety Regulation in the United States. USDA and FDA are the primary government organizations charged with protecting the food supply. Until recently, regulation of the safety of meat and poultry products was done largely through an inspection system (begun in 1906) that relied heavily on the visual examination of carcasses. This procedure is still done, but to update the inspection system, in 1995 the USDA required meat and poultry processing plants to adopt a system known as HACCP (hazard analysis and critical control points). HACCP is endorsed by the FDA, which regulates the majority of other food products not regulated by, USDA. HACCP is also endorsed by the National Academy of Sciences, the Codex Alimentarius Commission (an international food safety organization), and the National Advisory Committee on Microbiological Criteria for Foods. Regulations were put in place in December 1995 by the FDA requiring the use of HACCP in certain seafood processing operations. FDA also established HACCP regulations for the juice industry in 2001. Pilot HACCP studies involving cheese, bread, flour, and other products are currently in progress.

The HACCP system provides a rational approach to the control of microbial hazards in food. First presented at the 1971 National Conference on Food Protection, the HACCP system consists of seven principles: (1) identification and assessment of hazards associated with growing, harvesting, processing, marketing, preparation, and use of a given raw material or food product; (2) determination of critical control points to control any identifiable hazard; (3) establishment of preventive measures with limits for each control point; (4) establishment of systems to monitor critical control points; (5) establishment of corrective actions; (6) verification of properly working systems; and (7) effective recordkeeping.[339] When used as part of a regulatory system, HACCP is generally combined with microbial or other standards, to provide verification that the production process is "under control."

Some food products, like eggs, are covered by multiple jurisdictions. State, county, and local health departments have jurisdiction over food-preparation facilities, such as restaurants, cafeterias, and other places where food is prepared for public consumption.

Fresh produce has become increasingly implicated in foodborne outbreaks. Appropriate approaches to development of regulatory systems for produce are under investigation. Currently, FDA relies primarily on Good Agricultural Practice guidelines for minimizing risk associated with such products. However, the recent proliferation of outbreaks has raised questions about the effectiveness of this approach, and the need for develop of HAACP systems for produce.

11.1.2. Methods to Further Reduce Foodborne Bacterial Disease

11.1.2.1. Control of Pathogens in Animal Reservoirs. For zoonotic pathogens such as *Salmonella, Campylobacter*, and STEC that colonize the gastrointestinal tracts of animals without causing illness, elimination may be difficult. Crowded feeding lots and animal housing facilities promote cyclic reinfection and continuation of these pathogens. Furthermore, prolonged use of antibiotics may promote the growth of resistant pathogens. However, it may be possible to reduce the prevalence of these organisms on farms and in individual animals. As more is learned about the ecology of these organisms, better control measures can be instituted. For example, epidemiological studies have shown that *Campylobacter* may be introduced into chicken houses through contaminated water. Therefore, use of chlorinated water may decrease the prevalence of *Campylobacter*. Vaccination of chickens against *Campylobacter* may be another useful intervention. Another example of this sort of protective measure is the 2003 California ban of oysters imported from the Gulf Coast during certain months unless they are treated to reduce harmful bacteria, such as *Vibrio* spp. Treatment involves two FDA-approved methods: low-temperature pasteurization and high-pressure processing.[340]

Other foodborne pathogens have been successfully controlled or eliminated in animal reservoirs. A brucellosis eradication program by the USDA eliminated *Brucella melitensis* from sheep and has markedly decreased the prevalence of *B. abortis* in cattle. Other opportunities to con-

Table 8. Prevalence of Various Pathogens Sampled at Slaughter Plants in the United States

Pathogen	Product sampled			
	Steer/heifer carcasses[a] (2089 samples) (%)	Raw ground beef[b] (563 samples) (%)	Raw ground chicken[c] (285 samples) (%)	Raw ground turkey[d] (296 samples) (%)
C. perfringens	2.6	53.3	50.6	28.1
S. aureus	4.2	30.0	90.0	57.3
L. monocytogenes	4.1	11.7	41.1	30.5
C. jejuni/C. coli	4.0	0.002	59.8	25.4
E. coli O157:H7	0.2	0	0	0
Salmonella	1.0	7.5	44.6	49.9

trol pathogens in animals include controlling breeding stock, using effective vaccines, and implementing other on-farm controls to decrease carriage of pathogens.

11.1.2.2. Control of Pathogens in Plants. The control of pathogens in plants is complicated by the persistence and survival of some organisms in the environment. Irrigation and flood water or manure containing untreated animal or human waste can be potential sources of contamination. Prevention of bacterial pathogens in certain produce is difficult due to large surface areas and certain plant structures that can accumulate bacteria. Once internalized, the pathogens are difficult to remove. Scientists are investigating new technologies that would eliminate contaminants from fresh produce. Some suggestions have included irradiation of high-risk foods and washing produce with chemically altered water.

11.1.2.3. Control of Pathogens During Food Production. A number of innovative approaches are currently being used to prevent or minimize contamination of meat, poultry, and seafood by pathogens. The major source of pathogens on meat and poultry is the gastrointestinal tract of animals (with subsequent transfer to the hide or feathers), although environmental organisms can also be found on these foods. Table 8 shows results of a microbiological survey of raw meat products conducted by the USDA. For fish and other seafood, which frequently must be harvested under difficult conditions and at varying distances from processing, transport, and retail facilities, contamination may be from numerous sources, including the environment. In animal slaughter establishments, several methods are being used to reduce microbial contamination on carcass surfaces, including washing exterior surfaces of carcasses prior to slaughter, steam vacuuming of carcass surfaces during slaughter, and applying antimicrobial treatments to carcass surfaces immediately after slaughter.

11.1.2.4. Improvement of Food-Handling Practices. Food-handling errors frequently contribute to foodborne illness, allowing pathogens already present on foods to multiply to levels sufficient to cause illness. Such errors identified in outbreak investigations during a 15-year period included improper holding temperature (87%), poor personal hygiene (59%), inadequate cooking (56%), and contaminated equipment (47%).(8)

Pathogens on raw food products are the major source of foodborne illness. Independent retail food studies have shown varying levels of pathogen prevalence in raw produce and raw poultry and meats. Persons handling and preparing raw food products, including the producer, processors, food service personnel, and the public, must have the knowledge necessary to control microbial hazards. The level of knowledge needed by each group depends on the role it plays in the overall process. In homes and food service establishments especially, it must be emphasized that improper food-handling practices, such as leaving foods in ovens at low temperatures or at room temperatures or placing food in large containers prior to chilling, result in foodborne illness.(341)

Targeting specific education programs for persons at high risk should be a part of any consumer education program. For example, pregnant women should be advised of the potential risk of acquiring listeriosis from consuming certain soft cheeses and ready-to-eat foods. Persons with liver disease should be advised to avoid eating raw seafood. Immunocompromised persons, such as those undergoing cancer chemotherapy or those who have AIDS should be advised to avoid specific foods and take extra precautions in food handling and preparation. Consumers are also encouraged to thoroughly wash all raw produce before consumption.

Numerous publications are available from the FDA, FSIS, and other federal, state, and local government agencies on proper food handling. Educators, trainers, and organizations developing education and training materials for food workers and consumers may obtain information from the Foodborne Illness Education Information Center or online at www.foodsafety.gov.

11.2. Antibiotics and Chemotherapeutics

Antibiotics generally have no role in prevention of foodborne illness and in some cases may predispose individuals to infection with gastrointestinal pathogens or post-infection chronic sequelae. Occasionally, treatment of persons infected with such pathogens as *Shigella* may be warranted in order to prevent secondary transmission. Much attention has also been given to the use of antibiotics in animal feed. Subtherapeutic levels of antibiotics are routinely given to livestock in order to reduce animal disease and promote growth. There is increasing scientific evidence for cross-resistance, whereby bacteria in livestock develop antibiotic resistance and humans become infected with the resistant bacteria after consuming or handling contaminated meat. There are programs in place to describe the extent to which antibiotic resistance occurs. One such program, the National Antimicrobial Resistance Monitoring System (NARMS), is a multi-agency program headed by the FDA. NARMS monitors isolates collected from humans, farm animals, and retail meats for changes in antimicrobial drug susceptibilities of select enteropathogens.

11.3. Immunizations

Immunizations, with few exceptions, have little role in the control of foodborne illness. Typhoid fever, which may be spread through the foodborne route, is readily preventable through vaccination (see Chapter 43). New oral cholera vaccines show promise, but are not widely available (see Chapter 12). Vaccination against β-toxin has proved successful in controlling pig-bel in Papua New Guinea.

12. Unresolved Problems

The largest unresolved problem in this group of foodborne illnesses is determining the pathogens that make up the significant number of foodborne disease outbreaks with "unknown" etiology. While some of these outbreaks may be due to known pathogens, others await recognition. Also, the emergence of new pathogenic strains will continue to challenge the medical and public health communities; *E. coli* O157:H7 is an excellent example of this.

Underreporting of disease is another serious public health problem. Because most persons regard diarrhea as an inconvenience rather than a symptom of disease, the vast majority of diarrheal episodes do not result in visits to physicians, even though persons may be incapacitated for several days. A CDC study on self-reported diarrheal illness in FoodNet sites between 1998 and 1999 found that only 28% of individuals with symptoms sought medical care.[342] Lack of stool specimen submission is also a concern. A 1996 physician survey concluded that 44% of physicians requested bacterial stool culture. Other factors that contribute to underreporting of foodborne illness are occasional (rather than routine) laboratory testing for various pathogens and neglecting to report confirmed cases even when required. For these reasons, assessments of the impact of foodborne illness have always relied heavily on estimates and assumptions. A 1999 CDC study used underreporting multipliers to estimate that foodborne disease causes approximately 76 million illnesses and 5,000 deaths each year in the United States.[10] The Economic Research Service (ERS) of the USDA estimates that in 2000 the five major foodborne pathogens (*E. coli* O157, *E. coli* non-O157 STEC, *Listeria*, *Salmonella*, and *Campylobacter*) cost 6.9 billion dollars in medical costs, lost productivity, and premature deaths.[343] Other estimates yield a cost of 17 billion dollars for all foodborne deaths alone.[344]

As the number of goods imported by the United States increase, so does the concern over the safety of these imports. As globalization of the food supply expands, federal agencies must continue to ensure the safety of the food supply by increasing the number of inspections for microbiological and chemical hazards and by improving regulations for production of imported foods.

Finally, consumers and industry must be educated on the adverse effects of improper food handling and ways to eliminate bacteria that may already be present in raw foods. We must also look to new approaches for maintaining sustainable levels of livestock production without the use of veterinary antibiotics that have been linked to human antibiotic resistance.

CHAPTER 7

Botulism

Patricia A. Yu, Susan E. Maslanka, Michael E. St. Louis, and David L. Swerdlow

1. Introduction

Botulism is a neuroparalytic illness resulting from the action of a potent toxin produced by the organism *Clostridium botulinum*. Foodborne botulism is rare, but it may kill rapidly, and contaminated products may theoretically expose many persons to the toxin. Foodborne botulism therefore represents a medical and a public health emergency that places a premium on rapid, effective communication between clinicians and public health officials.

Depending on the mode of acquisition of the toxin, there are four distinct forms of botulism. Foodborne botulism results from the ingestion of food containing preformed toxin. Wound botulism is caused by organisms that multiply and produce toxin in a contaminated wound. Infant botulism is due to the endogenous production of toxin by germinating spores of *C. botulinum* in the intestine of the infant. Adult botulism from intestinal colonization is difficult to diagnose, but is suggested by those cases in which no food vehicle can be identified, there is no evidence of wound botulism, and there is evidence of prolonged excretion of toxin and *C. botulinum* in stool. Two other forms of botulism include iatrogenic, which occurs less commonly, and bioterrorism associate botulism, which theoretically could occur botulinum toxin was ever used as a bioterror weapon.

The seven botulinum toxin types of *C. botulinum* (A–G) are antigenically distinguishable. Types A, B, E, and, in rare cases, F cause disease in humans. Types C and D cause disease in birds and mammals. Type G, identified in 1970, has not yet been confirmed as a cause of illness in humans or animals. Important epidemiological features and some clinical characteristics distinguish the types of botulism that cause human illness. Rare cases of infant and adult botulism cases have been confirmed to be the result of intestinal colonization by non-botulinum *Clostridium* species that were able to produce botulinum neurotoxin such as *C. baratii* and *C. butyricum*.

2. Historical Background

In the late 18th century, a syndrome characterized by muscle weakness and respiratory failure linked to eating blood sausage was described and termed "sausage poisoning." Similar outbreaks related to sausage, other meats, and fish were reported in Germany, Scandinavia, and Russia. In time, the syndrome became known as "botulism" after "botulus," the Latin word for sausage.

In 1897, Van Ermengem detected the potent neurotoxin in a ham implicated in an outbreak of botulism in Belgium and isolated an organism that produced the toxin and grew only in the absence of oxygen. In a series of pioneering microbiological experiments, he determined that (1) foodborne botulism is not an infection, but rather an intoxication caused by a toxin produced in the food by the bacterium; (2) the bacterium will not produce toxin in food if the salt concentration is high enough; (3) the toxin is heat-labile; (4) the toxin when ingested with contaminated food is resistant to acid and proteolytic enzymes; and (5) not all animal species are affected equally by ingested toxin.

In 1904, Landman first identified a nonmeat product (home-canned beans) as the cause of an outbreak of botulism. During and shortly after World War I, the practice of home-canning vegetables increased markedly, as did the

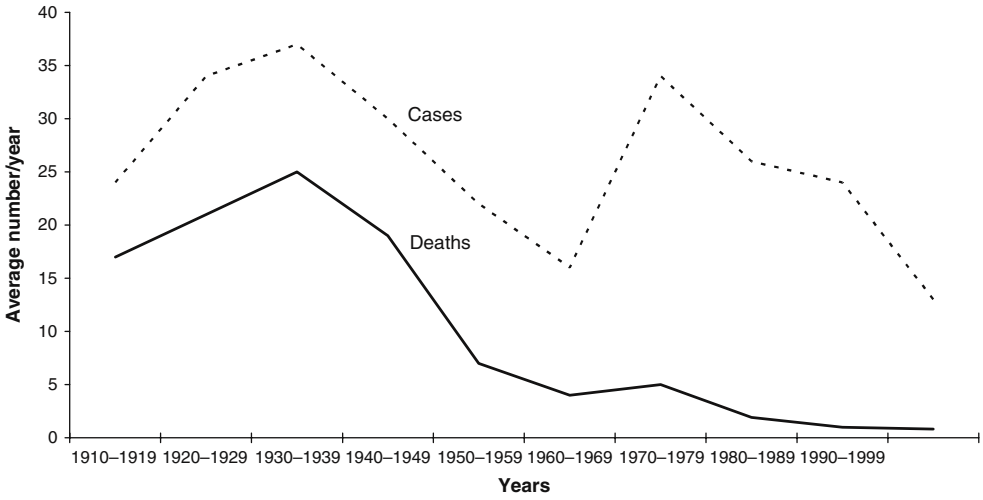

Figure 1. Average annual number of cases and deaths from foodborne botulism, United States, 1899–2006.

number of cases of botulism. Meyer made major contributions to the understanding of botulism during these years, studying the distribution of spores in soil in the United States and Europe, characterizing the epidemiology of botulism transmitted by home-canned vegetables and fruits, and even identifying a new type of *C. botulinum*.[1] In the mid-1940s, with the increased availability of refrigeration and the widespread application of improved preservation methods both in the home and by industry, the incidence of botulism began to decline. In recent years, increases in the incidence of botulism coincided with occurrences of large restaurant-associated outbreaks including 59 cases in 1977 (peppers), 20 cases in 1985 (sautéed onions), 36 cases in 1985 (chopped garlic in soybean oil), and 17 cases in 1994 (skordalia dip) (Figure 1).

Although it had been noted earlier that the toxins of the Van Ermengem and the Landman strains were serologically distinct, it was in 1919 that the first two type designations (A and B) were established. The types were based on strains isolated in the United States and could not be directly related to the earlier European strains, since the latter were no longer available for study. *C. botulinum* types C and D were discovered in relation to outbreaks of botulism in domestic birds and animals. *C. botulinum* type E was first isolated in 1936, from fish implicated in a botulism outbreak. *C. botulinum* type F was first isolated and recognized as a cause of human botulism in 1960. In 1970, *C. argentinense*, formerly *C. botulinum* type G, was isolated from soil in Argentina, but although there have been reports of isolation of the organism from human autopsy specimens, it has not yet been confirmed as a cause of botulism.[2] Neurotoxigenic strains of *C. baratii*[3] and *C. butyricum*[4] have been implicated in type F and type E human botulism, respectively.

3. Methodology

3.1. Sources of Mortality and Morbidity Data

The Centers for Disease Control and Prevention (CDC) maintains surveillance of botulism in the United States. The sources of morbidity and mortality surveillance data include (1) state, territorial, and local health departments (botulism is a reportable disease in all states); (2) state and territorial public health laboratories that contact CDC for laboratory support; (3) the US Food and Drug Administration, which becomes involved if the implicated food item is commercially produced or distributed; (4) the US Department of Agriculture, which becomes involved if the contaminated food item is derived from meat, poultry, or eggs; (5) clinicians who contact CDC for consultation, laboratory support, or antitoxin; and (6) the manufacturers of antitoxin, who are sometimes contacted initially by a patient's physician.

CDC provides epidemiological consultation to state health departments for suspected non-infant botulism cases and laboratory diagnostic services for infant and non-infant cases for samples from state health departments that do not conduct botulism laboratory testing. In addition, CDC monitors and authorizes the release of botulinum antitoxin for non-infant cases. The California Department of Health Services provides clinical consultation, laboratory diagnostic services for infants residing in California, and human botulism immune globulin intravenous (BabyBIG®) to state

health departments for suspected infant botulism cases. In spite of this surveillance, it is possible that underreporting of botulism occurs as a result of misdiagnosis of cases (as, for example, myasthenia gravis, Guillain–Barré syndrome, or stroke). Mild cases of botulism may escape diagnosis because of a lack of overt neurological findings, and even severe cases resulting in death may be diagnosed only after death, if at all.[5,6] Missed cases of botulism are an important public health problem, because lack of recognition precludes epidemiological investigation and prevention of subsequent cases due to the same contaminated foods.[5,7]

3.2. Laboratory Confirmation

Since botulism results from the action of a toxin, the most definitive laboratory confirmation of the disease is the demonstration of the toxin itself in clinical specimens (serum, feces, wound, or gastric aspirate) or foods.[8] Isolation of *C. botulinum* organisms from foods are not definitive, as the organisms may be present in food products that do not support toxin production. On the other hand, isolation of *C. botulinum* from human cultures of feces is very rare except in persons suspected of having botulism, and may be considered strong evidence supporting the diagnosis.[9] Because of the delays inherent in laboratory confirmation, the initial treatment decisions should be made on the basis of patient signs and symptoms that are consistent with botulism.

The mouse bioassay is currently the most sensitive, specific, and commonly used method for detecting botulinum toxin in foods and cultures, and there is no other method approved for testing clinical specimens collected from suspect botulism patients.[8,10] A standard volume of the test specimen (e.g., an aliquot of serum or extract of feces or food) is injected into the peritoneum of test mice and from this site is absorbed into the bloodstream. The same volume of test specimen is combined with selected botulinum antitoxins and injected into the peritoneum of control mice. Experienced laboratory workers can recognize the clinical manifestations of botulism in the mouse. The clinical diagnosis is confirmed if samples injected into mice produce paralytic signs consistent with botulism and mice injected with sample mixed with toxin-specific antitoxin have no paralytic signs. While test results are usually available within 24 h of specimen receipt, very low levels of toxin may not produce botulism signs in mice for up to 96 h. Some medications administered to patients and on rare occasion some food matrices may prevent the observation of botulism signs; however, experienced laboratory personnel can readily differentiate between these non-specific signs and those caused by botulinum toxin. This test can only be performed in select laboratories because it requires animals and experienced laboratory personnel who can perform these tests safely and have the expertise to recognize botulism signs in mice.

Much effort has been made for the development of satisfactory in vitro assays for botulinum toxin. The status of studies on immunodiffusion, passive hemagglutination, immunofluorescence, radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), and biosensors have been reviewed.[11] ELISA is more rapid than the mouse bioassay and the technology is readily available in laboratories, however, it is less sensitive than the mouse bioassay, some cross-reactivity may be observed, it only detects four toxin types, and is not currently approved in the United States for clinical specimens.[12] ELISA is an effective, rapid screening method with results confirmed by mouse bioassay. Real-time PCR is a method of rapid detection of all seven botulinum neurotoxin genes in cultures of clinical specimens and foods.[13] However, this test must be used in conjunction with a method that can detect toxin because (1) multiple neurotoxin genes may be detected but the strain may only produce one botulinum toxin type and (2) *C. botulinum* spores are ubiquitous in the environment, including foods, and may be present without being the cause of disease. Mass spectrometry is another in vitro method that is more rapid than the mouse bioassay and is sensitive in detecting and differentiating four toxin types A, B, E, and F.[14] Pulsed-field gel electrophoresis (PFGE) has been used to differentiate strains of *C. botulinum* for molecular epidemiologic analysis.[15,16] Nevertheless, because of the extraordinary biological potency of botulinum toxins, the mouse bioassay due to its superior sensitivity and specificity remains the method of choice for laboratory investigations of botulism. The mouse bioassay is also remarkable in that it allows the detection of any type of botulinum toxin, including any types waiting to be discovered in the future. This is because experienced laboratory personnel can identify the signs of botulism in mice and this identification is independent of the use of antitoxins used for toxin neutralization. Since all in vitro methods developed so far depend on specific antibody to capture toxin (either on microplate or microbeads), the mouse bioassay is the only method capable of demonstrating the action of a new type of botulinum toxin that is antigenically distinct from those currently recognized.

Efforts have been made to prepare laboratories to respond to botulism-related bioterrorism. The Laboratory Response Network (LRN) is a network of state and local public health, federal, and military laboratories in the United States and internationally. The mission of LRN is to maintain an integrated national and international network of laboratories that are fully equipped to respond quickly to acts of chemical or biological terrorism, emerging infectious diseases, and other public health threats and emergencies.[17]

LRN's botulism-related activities include providing to member laboratories agent-specific procedures and standardized reagents and controls, a laboratory referral directory, and secure access for e-mail regarding training and emergency communications.

4. Biological Characteristics of the Organism

C. botulinum is not a single species but rather a group of culturally distinct organisms that are alike only in that they are *Clostridia* and produce antigenically distinct neurotoxins with a similar pharmacological action. The seven types of *C. botulinum* (A–G) are distinguished by immunologically distinct types of toxin. *C. botulinum* organisms have also been divided into group I (proteolytic; type A and some strains of types B and F), group II (nonproteolytic; type E and some strains of types B and F), group III (types C and D, which are closely related to *C. novyi*), and group IV (*C. argentinense*, formerly *C. botulinum* type G[18,19]). *C. botulinum* organisms are straight to slightly curved, gram-positive (in young cultures), motile, anaerobic rods, 0.5–2.0 μm in width by 1.6–22.0 μm in length, with oval, subterminal spores.[20] Demonstration of the ability to produce botulinum toxin is critical to the identification of neurotoxin producing *Clostridia* species since nontoxigenic equivalents exist. *C. sporogenes* are indistinguishable from *C. botulinum* group I strains and show DNA homology, but do not produce toxin. Cases of human botulism due to other species of *Clostridia*, *C. baratii*[3] and *C. butyricum*,[4,21] have further strained the taxonomic classification of botulism-causing organisms. All typical *C. baratii* and *C. butyricum* strains are biochemically identical to the neurotoxin producing strains, but do not contain the genes necessary to produce botulinum toxin.

The specific cultural and biochemical characteristics of *C. botulinum* are described elsewhere.[20,22] Because of the practical importance of temperature, salt concentration (water activity), and pH in the preservation of foods, the effects of these factors on the growth of *C. botulinum* have been thoroughly investigated. All strains of *C. botulinum* are mesophilic, growing best at 40°C; although some nonproteolytic strains have been noted to grow at temperatures as low as 3°C.[23] The organism will generally not grow in an acid environment (pH <4.6) or in foods with a high salt content (water activity <0.93). Temperature, pH, and salt content are interrelated factors; lowering the pH or raising the salt concentration increases the minimum temperature at which spores will germinate or vegetative cells will begin to grow.[24]

The ability of *C. botulinum* to cause food poisoning in humans is directly related to the production of heat-resistant spores that survive preservation methods that kill nonsporulating organisms.[25] The heat resistance of spores varies from type to type and even from strain to strain within each type; although some strains will not survive at 80°C, spores of many strains require temperatures above boiling to ensure destruction.[26,27] The thermal resistance of spores also increases with higher pH and lower salt content of the medium in which the spores are suspended.[28] In general, type A and proteolytic type B spores are more heat-resistant than type E and nonproteolytic type B spores. Spores are also susceptible to some types of radiation.[27,29,30] Nitrites are effective as well in preventing growth from spores that germinate[30] and are used commercially in semiprocessed meats.

C. botulinum types C and D have bacteriophages that are associated with toxigenicity. Nonlysogenic, nontoxigenic mutants have been obtained by "curing" them of their phages. These mutants can be made lysogenic and toxigenic again by infection with phages obtained from other lysogenic strains.[31] Hence, the ability of *C. botulinum* types C and D to produce toxin seems to depend on the presence of specific bacteriophages. No association between bacteriophages and toxigenicity has been found, however, for type A, B, E, and F strains of *C. botulinum*. The association between lysogenization by phage and toxin production has been noted with *Corynebacterium diphtheriae*. The genetic information for the production of neurotoxin by *Clostridium tetani*, however, appears to be located on a plasmid.[32] Recent evidence has found that neurotoxin genes of at least some strains of *C. botulinum* serotypes A and B are located on plasmids.[33]

Toxin is released from *C. botulinum* organisms only after lysis of the cells. The lytic enzymes responsible for this autolysis are located in the cell wall. More than one such bacteriolysin has been identified, and at least some appear to be group specific.[34]

5. Descriptive Epidemiology

5.1. Foodborne Botulism

Botulism has been reported from all parts of the world, although the causative strains of *C. botulinum* and the characteristic food vehicles responsible for botulism may vary widely among regions. Botulism in continental Europe is almost exclusively type B disease and is predominantly caused by eating home-cured hams. The resulting illness is relatively mild and slowly progressive compared with botulism in the United States.[35] Most outbreaks in Japan are type E botulism associated with the consumption of preserved seafood.[36,37] In Canada, type E botulism outbreaks associated with seafood preserved by First Nations and Inuit populations is most common.[36,38] In China, where

home-fermented bean curd is the most common vehicle of botulism poisoning, the causative strains are a mixture of types A and B.[39] Illness is more severe and case-fatality ratios are substantially higher for type A than for type B botulism in the United States,[8,40] but are marginally higher for type B than for type A botulism in China.[39] In 1991, a large outbreak of type E botulism occurred in Egypt, traced to consumption of faseikh, a fermented fish dish eaten since the time of the Pharaohs.[41] The Republic of Georgia has the highest incidence of foodborne botulism in the world, primarily attributable to unsafe home-conservation methods of preserving vegetables (mostly type B), while smoked fish and other food products also cause some illnesses.[42] Other outbreaks outside of the United States have included type E botulism due to smoked vacuum-packed whitefish in Finland and Germany,[43,44] type A botulism due to bamboo shoots in three separate outbreaks in Thailand,[45,46] food items served at a barbeque in Austria,[47] roasted canned mushrooms in Turkey,[48] type A botulism due to commercially produced tinned fish in tomato sauce in South Africa,[49] type A botulism due to commercial mascarpone cheese in Italy,[50] and traditional Maori home-canned tiroi made with watercress and mussels in New Zealand.[51,52]

In the United States between 1899 and 2006, 1,152 outbreaks of foodborne botulism involving 2,672 persons were reported. The mean annual incidence of reported foodborne botulism in the United States in 1997–2006 was 0.1 cases per 1,000,000 persons. Generally, the northern and western states in the contiguous United States have had higher rates of foodborne botulism than the southern and eastern states. Alaska had the most cases (76) between 1997 and 2006 and had by far the highest rate of reported botulism in the United States (12 cases per 1,000,000 population).[53]

Since botulism in adults most commonly results from eating improperly preserved home-canned (or home-bottled) foods, outbreaks usually occur in family groups and affect small groups of people. In recent years, however, novel vehicles of foodborne botulism in the United States have been reported. These differ in being "fresh" rather than preserved food, and include potato salad,[54,55] baked potatoes,[56,57] sautéed onions,[58] commercial potpies,[59] turkey loaves,[56] beef stew,[56] contraband alcoholic beverage prepared by prison inmates,[60] tea made from peyote[61] and fermented tofu.[62] In each case, these unpreserved foods were prepared by ordinary cooking procedures (which do not kill *C. botulinum* spores) and then stored for many hours to days under relatively anaerobic conditions (e.g., baked potatoes in foil, sautéed onions under melted butter) at temperatures warm enough to encourage the outgrowth of spores and to support toxin production. The foods were then eaten without having been thoroughly reheated to a temperature that could destroy the heat-labile toxin. Homemade foods accounted for 67% of foodborne botulism events in 1990–2000, of which 69% were home-canned foods.[63]

Food that is commercially prepared or distributed may cause illness in a large number of persons who may be spread over a wide geographic area.[7,55,64–66] Since 1976, large outbreaks of botulism have increasingly occurred in association with foods served in restaurants; although such outbreaks constituted only 4% of botulism outbreaks in 1976–1984, these outbreaks accounted for 42% of all foodborne cases of botulism.[67] From 1990 to 2000, restaurant-prepared foods accounted for 22% of botulism outbreaks and affected 16% of all foodborne botulism cases.[63] Commercially prepared and distributed chili sauce has been implicated in two outbreaks in the United States. One occurred in 2003 and involved 15 cases in Texas.[64] This outbreak was the first outbreak that implicated food improperly refrigerated and stored at a salvage store. The other chili sauce outbreak occurred in 2007 and involved eight cases in Indiana, Ohio, and Texas.[66] This outbreak was caused by deficiencies in the commercial retort canning process, resulting in approximately 111 million cans recalled in 2007 (until this outbreak, there were no reported cases associated with commercial canning in the United States in over 30 years and this outbreak was the largest US botulism outbreak associated with commercial canning since 1919). A novel food vehicle, carrot juice, was the cause of an international outbreak involving six cases in Florida; Georgia; and Ontario, Canada in 2006. It was likely that the commercial carrot juice was inadequately refrigerated either during transport, storage by the retailer, or storage by the patients.[65] Such large outbreaks of botulism often result in extraordinary economic costs as well as extensive morbidity.[68,69] Long-term negative health effects of botulism illness have been documented.[69–74] In a case–control study conducted in the Republic of Georgia between 1998 and 2003, cases (mostly foodborne, type B botulism) after a median of 4.3 years after their botulism illness were more likely than controls to suffer from fatigue, weakness, dizziness, dry mouth, difficulty breathing while walking or lifting heavy items, and experiencing other physical or emotional problems interfering with normal activities.[72]

Although foodborne botulism affects all age groups, it occurs mainly in persons aged 30–60 years.[63,75,76] This age distribution may reflect that of persons who eat home-canned foods. Although it has been hypothesized that younger persons may be less susceptible to botulism, evidence indicates that the lower case-fatality ratios for the younger age groups are due to fewer complications during intensive respiratory support rather than to inherent resistance to the effects of botulinum toxin.[77] The disease occurs with nearly equal frequency in men and women. Rates of botulism cases reported to CDC are shown in Figure 1.

Corresponding to the distribution of botulinum spores in soil samples,[78] between 1985 and 1994, 80% of botulism outbreaks that occurred in the western United States (excluding Alaska) were type A and 19% were type B, compared with outbreaks east of the Mississippi River, where 65% of outbreaks were due to type A and 30% were due to type B. In Alaska, approximately 89% of outbreaks were of type E botulism during this period; outbreaks in Alaska have uniformly been due to fermented or otherwise preserved fish or aquatic mammals.[63,79]

5.2. Infant Botulism

Since 1980, infant botulism is the most common form of botulism reported in the United States. It is epidemiologically distinct from foodborne botulism, representing the effect not of ingestion of toxin preformed in contaminated foods, but of colonization (infection) of the intestine by spores of *C. botulinum*, with subsequent in vivo toxin production.[80] Although infant botulism was first described in 1976,[81,82] earlier cases have been identified retrospectively, and its detection probably reflects advances in diagnostic capabilities rather than the emergence of a new clinical syndrome. Cases have been reported in the United States, Australia, Argentina, Canada, Chile, Czechoslovakia, France, Great Britain, Italy, Japan, Spain, Sweden, Switzerland, and Taiwan.[83]

In the United States, 2,382 cases were reported from 50 states to CDC between 1976 and 2006 (Figure 2). Since reporting began to stabilize in 1980, the average annual incidence of reported infant botulism in the United States has been approximately 1.9 in 100,000 live births. Since 1985, 46% of all infant botulism cases have been reported from California. The incidence is highest in Delaware, Hawaii, Utah, and California (9.0, 8.8, 6.3, and 5.7 per 100,000 live births, respectively), perhaps reflecting better diagnosis and reporting in those states.

The illness is confirmed by demonstrating botulinum toxin in and isolating *C. botulinum* from the infant's stool. Toxin may be detected in serum (13% of tested infants), more often in type A cases (36%) than in type B cases (2%).[84] In the United States, between 1997 and 2006, 41% of infant botulism cases were caused by *C. botulinum* type A and 57% by type B. Seven infant botulism cases in the United States were associated with type F toxin and caused by *C. baratii* (CDC, unpublished data). Two cases in Italy were associated with type E toxin and caused by *C. butyricum*.[21] *C. botulinum* isolates producing dual toxin types have been identified in botulism cases.[85,86] Infant botulism is first seen most commonly in the second month of life and occurs somewhat earlier in cases of type B disease (median 9 weeks) than in cases of type A disease (median 11 weeks). There is no sex predilection and no apparent pattern of seasonal variation.

Infants hospitalized with the disease tend to have had higher birthweights than other infants, and their mothers tend to be white, older, and better educated than mothers in the general population. Affected infants are also more commonly breast-fed[87,88]; breast-feeding is associated with an older age at onset in type B cases.[88] Clustering of cases of infant botulism has been noted in some suburban areas in the eastern United States and in small towns and rural areas of apparent high incidence of infant botulism in the West.[89–91]

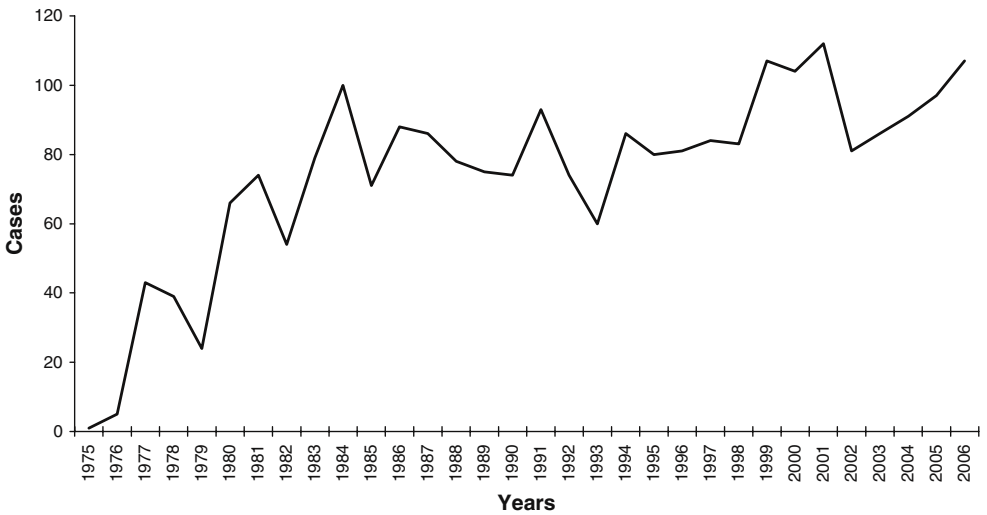

Figure 2. Cases of infant botulism reported to the Centers for Disease control and Prevention, United States, 1976–2006.

Evidence of infant botulism was detected in several cases of sudden infant death syndrome (SIDS) in Argentina, Australia, Finland, Germany, Italy, and the United States.[87,91–98] The similar age distribution of infant botulism and SIDS contributed to the hypothesis that unrecognized infant botulism might be an important cause of SIDS. One such case was an 11-week-old patient in Finland whose death was classified as SIDS and may have been a case of infant botulism.[92] *C. botulinum* isolates from the patient's intestinal contents and from his household's vacuum cleaner dust bag were confirmed to produce botulinum toxin with a mouse bioassay. In addition, two molecular typing methods, pulsed-field gel electrophoresis (PFGE) and randomly amplified polymorphic DNA (RAPD), could not distinguish the clinical specimen isolate from the vacuum cleaner dust bag isolate.

5.3. Wound Botulism

Wound botulism is a rare disease resulting from the growth of *C. botulinum* spores in a contaminated wound with in vivo toxin production.[99] Between 1943, when the syndrome was first recognized, and 2006, 390 cases of wound botulism were reported in the United States. Of 382 laboratory-confirmed cases in the United States from 1973 to 2006, 337 (88%) were type A, 33 (9%) type B, 1 (<1%) a mixture of type A and type B organisms, and 11 (3%) had serum quantity insufficient to do toxin-specific neutralization.[60] The median age of the patients was 41 years (range 5–67 years); 70% were male. The case-fatality rate was 4%. The wounds were usually deep and contained avascular areas; many patients had compound fractures, and four had extensive crush injuries of the hand. The median incubation period in cases of trauma was 7 days (range 4–21 days).[100]

The first wound botulism case associated with injection drug use occurred in a New York City patient, who attempted to inject cocaine intravenously in 1981.[101] Since then, wound botulism has dramatically increased over the past two decades largely due to cases associated with injection drug use; these cases have been associated either with needle puncture sites or with nasal or sinus lesions due to chronic cocaine sniffing.[102–104] Between 1973 and 1989, the average number of wound botulism cases in the United States was two cases per year; 28% of cases were due to injection drug use. Between 1990 and 2006, the average number of wound botulism cases increased 10-fold to 20 cases per year; nearly all (98%) were due to injection drug use (CDC, unpublished data). In some cases, as in wound botulism cases caused by other sources such as crush injuries, the wounds may not be obvious or grossly infected. Chronic drug users may have multiple superficial wound infections or abscesses from injecting several times a day, making laboratory confirmation, which entails culture of the organism from wound, difficult. The major risk factors appear to be the practice of subcutaneous or intramuscular injection ("skin-popping") of black-tar heroin and race.[103] Since the late 1980s, black-tar heroin has become the predominant cause of wound botulism west of the Mississippi River in the United States. The production of black-tar heroin involves the use of adulterants such as ground paper fiber soaked in black shoe polish and possibly dirt, which may introduce contamination with *C. botulinum* spores. Heroin-associated wound botulism cases have also been documented in Europe since 2000.[105,106]

5.4. Child or Adult Botulism from Intestinal Colonization

Isolated cases of botulism in which extensive investigation failed to implicate a specific food as the cause of the disease have been recorded by CDC since 1978 as cases of "undetermined origin" rather than of foodborne botulism. Since 1978, there have been 49 such cases reported in the United States. Although there has been speculation on the matter since the 1920s, careful investigation has now demonstrated that some of these cases are caused by colonization of the gastrointestinal tract by *C. botulinum* and *C. baratii* with in vivo production of toxin, analogous to the pathogenesis of infant botulism.[2,107] Support for the diagnosis of botulism from intestinal colonization is provided by the demonstration of the prolonged excretion of toxin and *C. botulinum* in the stool. Definitive diagnosis of this form of botulism is difficult and in most cases relies on the absence of association with a botulinum toxin contaminated food. In some cases of botulism strongly suspected of representing intestinal colonization, the patients had preceding gastrointestinal surgery or illnesses, such as inflammatory bowel disease, that may have predisposed them to enteric colonization.[2] No other specific risk factors have been identified.

5.5. Iatrogenic Botulism

Iatrogenic botulism is caused by injection of botulinum toxin at high enough doses to cause systemic disease during the treatment of cosmetic or neurological disorders. In the United States, Botox® Cosmetic (botulinum toxin type A) is licensed and indicated for the treatment of blepharospasm, strabismus, cervical dystonia, severe primary axillary hyperhydrosis, and for the temporary improvement in the appear-

ance of moderate to severe facial frown lines. Myobloc® (botulinum toxin type B) is also approved in the United States and is indicated for the treatment of adults with cervical dystonia. Off-label use of botulinum toxin for the treatment of other conditions also occurs. In 2004, an outbreak of four botulism cases occurred in the United States and involved an unlicensed physician injecting himself and three others with a research-grade botulinum toxin type A product (unlicensed for cosmetic/human use), exposing each patient to as much as 21–43 times the estimated human lethal dose by injection.[108,109] The toxin was labeled as a laboratory research product, not licensed or intended for human use, and was ordered and shipped from a legitimate manufacturer. All four patients survived; one patient, who was followed up 10 months after hospitalization, reported persistent myalgias, muscle weakness, shortness of breath, and persistent pain that required treating with an analgesic medication.[104] Botulism associated with the use of botulinum toxin injections for reducing spasticity and dystonia in pediatric patients with cerebral palsy have also been documented.[60,105] Botulism-related syndromes in these patients may include ptosis, diplopia, dysphagia, dysarthria, dystonia, fatigue, and generalized muscle weakness. A review of patients with reported adverse events during and following administration of licensed botulinum toxin was conducted.[111] This study reviewed 1,437 reports of adverse events from 1989 to 2003 through MedWatch, a voluntary system for reporting adverse events, product quality problems, or product use errors. Serious adverse events reported in patients treated with licensed toxin type A for therapeutic reasons (for both labeled and unlabeled indications) covered a wide variety of reactions including death, dysphagia, muscle weakness/spasm, allergic reactions, flu-like syndromes, gastrointestinal symptoms, cardiovascular-system related symptoms, respiratory system-related symptoms, and seizure. No deaths were reported in patients treated with toxin type A for cosmetic purposes, but commonly reported reactions included headaches, focal facial paralysis, muscle weakness, dysphagia, flu-like syndromes, and allergic reactions.

6. Mechanisms and Routes of Transmission

6.1. Foodborne Botulism

Foodborne botulism is caused by consuming improperly preserved food in which spores of *C. botulinum* have germinated and organisms have grown and produced toxin. Home-processed foods accounted for 95% of foodborne botulism outbreaks in the continental United States in the past decade. Mass-processed commercial foods accounted for only 5% of outbreaks and 3% of cases. Even the large, restaurant-associated outbreaks of recent years have generally been caused by foods either home-canned in the restaurant[112] or otherwise improperly handled or stored,[7,58] rather than by defective commercially canned products.

Temperatures obtainable only with a pressure cooker are usually necessary to kill *C. botulinum* spores.[25,113] Boiling alone does not kill the spores of proteolytic strains, but does kill competing organisms and creates an anaerobic environment that will support the growth of *C. botulinum* once the spores germinate. The toxin itself is heat-labile; heating to 80°C for 10 min is sufficient to destroy the toxin. However, some home-canned foods are not cooked before being eaten, and those that are cooked may not be subjected to sufficient heat to destroy all the toxin present.

Although the epidemiological investigation of outbreaks has improved and the vehicles of botulism outbreaks have been more frequently identified in recent years, the proportional contribution of different types of food to cases of foodborne botulism has remained relatively stable (Table 1). Vegetables and fish/aquatic animals have continued to be the most common food vehicles in foodborne cases over the years. Vegetables, especially those of more neutral pH such as asparagus, green beans, peppers, and mushrooms, are responsible for most type A and type B outbreaks. Spores may survive when either hot-pack or cold-pack canning methods are used[113]; cold-pack canning is acceptable only for certain fruits because of their high acidity or low water activity due to their high sugar content, which inhibits outgrowth of *C. botulinum* spores. Type E outbreaks are most often caused by products derived from fish and marine mammals. For example, many type E outbreaks in Alaska are associated with "muktuk" and "stink eggs," in which whale blubber or fish eggs are fermented in an anaerobic milieu, allowing the outgrowth of *C. botulinum* organisms.[78,114]

Table 1. Vehicles of Foodborne Botulism in the United States, 1899–1977 (1961 Cases), 1978–1985 (235 Cases), 1986–1994 (227 Cases), and 1995–2006 (249 Cases)*

	Percent of total cases			
Vehicle (number of cases)	1899–1977 (1961)	1978–1985 (235)	1986–1994 (227)	1995–2006 (249)
Unknown	65.5	3.0	16.0	18.0
Identified	34.5	97.0	84.0	81.9
Vegetables	57.0	64.0	45.0	33.2
Fish/aquatic animals	15.6	19.3	45.0	45.8
Fruits	11.0	0.9	0	1.1
Condiments	8.7	10.1	4.7	1.6
Meat/dairy	7.5	5.7	3.7	18.4

6.2. Infant, Wound, and Child or Adult Botulism from Intestinal Colonization

In contrast to foodborne botulism, which is an intoxication, infant, wound, and child or adult botulism from intestinal colonization results from colonization by neurotoxin producing *Clostridia* species. These organisms are widely distributed in nature and can easily be ingested with foods[78,115] or contaminate a traumatic wound. The low frequency of *C. botulinum* infections despite the ubiquity of the organism in nature suggests that host factors are prominent in the epidemiology of these infectious forms of botulism.

Infant botulism results after colonization of the infant intestine.[80] In a prototypical case, type B organisms, but no toxin, were isolated from honey fed to an infant with infant botulism whose fecal specimens contained type B organisms and toxin. Family members who ate some of the same honey did not become ill. In several studies from the late 1970s and early 1980s, more than 20% of affected infants had ingested honey before the onset of botulism.[88,116,117] In many cases, *C. botulinum* spores of the same type were cultured from honey in the same households.

However, since most infants with infant botulism have had no exposure to honey, the risk factors and vehicles of transmission of *C. botulinum* for the majority of cases remain unclear.[80,118] A survey of foods commonly fed to infants revealed *C. botulinum* in specimens of corn syrup as well as honey, but in no other tested category of foods.[115] In other studies, the same types of *C. botulinum* that caused disease were isolated from soil in an infant's yard and from vacuum cleaner dust; investigators have also frequently noted environmental conditions that might expose infants directly to environmental sources of *C. botulinum* spores, such as a shared crib, dusty or windy locales, nearby building construction, or outdoor activities.[89,91] Infants hospitalized with botulism have also more typically been breast-fed than have control infants.[87,118–120] Breast-feeding is known to affect the fecal flora differently than formula feeding; in mice, the fecal flora have been shown to be an important susceptibility factor in challenge experiments with *C. botulinum* type A spores.[121]

Wound botulism, like tetanus, gas gangrene, and other clostridial diseases, can result from soil contamination of a wound.[100] Although the diagnosis of wound botulism may be frequently missed, the extreme rarity of wound botulism despite the wide distribution of the organism in the environment raises many questions regarding its pathogenesis: Are many wounds contaminated but few suitable for proliferation of the organism? Or is wound contamination with *C. botulinum* without signs of botulism truly uncommon? Data are scarce. Part of the problem is the difficulty in obtaining adequate anaerobic cultures and in differentiating *C. sporogenes* (a common wound isolate) from *C. botulinum*. In addition, the factors involved in spore germination, growth, and toxin production in tissues or in vivo systems have not been well studied.

In cases of adult botulism in which intestinal colonization was proven or suspected, vehicles have included canned cream of coconut[107] and blackberry preserves,[122] in each of which *C. botulinum* organisms of the appropriate type were detected. In a case strongly suggestive of this syndrome, a healthy, 27-year-old asymptomatic consumer of blood sausage was shown to have intestinal carriage of *C. botulinum* 19 days after an outbreak attributed to the sausage, but did not develop clinical symptoms and botulinum toxemia until 47 days after the outbreak.[2] The limited data about enteric infectious botulism in adults do not suggest that the vehicles of transmission are categorically different from those of traditional foodborne botulism due to preformed toxin.

7. Pathogenesis and Immunity

Incubation periods for foodborne botulism are reported to be as short as 6 h or as long as 10 days,[7] but generally the time between toxin ingestion and onset of symptoms ranges from 18 to 36 h.[40] Among patients with foodborne botulism, incubation periods are shorter for patients with illness from type E toxin.[40] The incubation periods for wound botulism (4–14 days) are longer than those usually seen in cases of foodborne botulism, and presumably reflect the time required for the multiplication of *C. botulinum* in the wound and the release of toxin. It has been shown that those individuals with shorter incubation periods—apparently those who ingest and/or absorb larger amounts of toxin—have more severe disease and a graver prognosis.[123] The incubation period has not been determined for cases of infant botulism.

Botulinum toxin is produced by the bacterial cell as a polypeptide chain with a molecular weight of 150 kDa (100 kDa heavy chain and 50 kDa light chain) and is noncovalently associated with other proteins (hemagglutinin, HA, and nontoxin nonhemagglutinin, NTNH). The complex is absorbed into the bloodstream from the gastrointestinal tract likely through a receptor-mediated endocytosis process. The complex disassociates in the bloodstream and botulinum toxin is transported via lymphatics and blood to cholinergic neuromuscular junctions. The mechanism for transport of botulinum toxin into the extracellular is not known. But here the toxin, through the heavy chain, is fixed at and then the light chain is internalized into the presynaptic nerve endings through receptor-mediated endocytosis and pH induced

translocation. The light chain, which is unique for each of the 7 toxin types, is a zinc-endopeptidase which cleaves a specific peptide sequence of one of several proteins involved in the release of acetylcholine from the nerve ending.[124] Blockade of acetylcholine release prevents muscle contraction and results in flaccid paralysis that is characteristic of botulism[125,126]. Evidence suggests that the binding of botulinum neurotoxin to the nerve ending is irreversible[126]; hence, functional recovery occurs only with the regeneration of neuronal fibrils and the reestablishment of the neuromuscular junction. The length of action of botulinum toxin may also be due to the internal half life of toxin or may be due to some unknown features specific to the protein substrates of the light chain. And these variables may be toxin-type dependent. This may explain why muscular weakness persists in many individuals for weeks or more after toxin has been eliminated from the intestine and bloodstream and why in severely affected individuals recovery may take many months to years or may never be complete.[58,71] Observation of patients has shown that patients with type A botulism (foodborne or infant) take longer to recover than those with type B or type E botulism. Differences in light chain stability and/or differences in recovery of protein substrate may explain the toxin type -dependent recovery rate in patients.

Botulinum toxin affects acetylcholine release only at peripheral sites; the central nervous system is not affected. Botulinum toxin does not appear to have the ability to cross the blood-brain barrier, but in vitro studies have shown that tissues of central nervous system origin are affected by the toxin's action.[124] Both the autonomic and voluntary motor activities of the cranial nerves seem to be uniquely susceptible to the effects of botulinum toxin. The cranial nerves are nearly always affected earlier and to a greater degree than are the nerves to the peripheral and respiratory muscles. Certain cranial nerves seem to be more sensitive to one botulinum toxin type than to others. Pupillary paralysis, for example, is apparently more commonly noted in type A botulism than in type B botulism.[40,71,77] Correspondingly, distinctions in the effect of type A and B toxin on laboratory preparations of the neuromuscular junction have been observed.[127] Although the reason for this is not clear, molecular differences between toxin types that account for immunologic distinction might, through stearic interactions, also result in disparate binding capabilities at neuromuscular junctions.

Botulinum toxin is typically so potent that the lethal dose is far below that required to induce an antibody response. In one case of adult intestinal colonization, protective antibodies developed and remained at a protective level for more than a year.[128]

Animal models of infant botulism have yielded insight into mechanisms of intestinal colonization and in vivo growth of *C. botulinum*. Successful intraintestinal colonization by *C. botulinum* spores inoculated into the stomachs of infant mice is strongly age-dependent, peaking at 7–13 days old, a period during which the enteric microbial flora are in transition.[129] Although normal adult mice are highly resistant to colonization, germ-free adult mice may develop botulism after ingesting as few as ten spores,[130] and antimicrobial treatment of normal adult mice dramatically lowers the dose of ingested spores necessary to yield intraluminal outgrowth and production of toxin.[131] In mice, therefore, enteric infection is limited to a narrow age range in infancy and to occurrence in adults that have undergone a manipulation of the normal intestinal microbial flora. It is possible that anatomic variations, stasis, or constipation due to mechanical or motility factors or some combination of these contribute to the creation of an environment favorable to the growth of the organism.

Factors other than just the physical production of toxin in the gut may also contribute to the expression of clinical illness. *C. botulinum* organisms and toxin have been recovered from the feces of human infants more than 8 weeks after the onset of botulism, and the peak excretion of toxin may not occur until several weeks after the illness has already begun to resolve.

8. Patterns of Host Response

8.1. Clinical Features

The clinical syndrome of botulism, whether foodborne, infant, wound, or adult or child intestinal colonization, is dominated by the neurological symptoms and signs resulting from a toxin-induced blockade of the voluntary motor and autonomic cholinergic junctions and is essentially quite similar for each syndrome and toxin type.[77,80,100,120] The ingestion of other bacteria and their toxins in the improperly preserved food may account for the abdominal pain, nausea and vomiting, and diarrhea that often precede or accompany the neurological symptoms of foodborne botulism. Dryness of the mouth, inability to focus to a near point (prompting the patient to complain of "blurred vision"), and diplopia are usually the earliest neurological complaints. If the disease is mild, no other symptoms may develop and the initial symptoms will gradually resolve. The person with mild botulism may not come to medical attention. In more severe cases, however, these initial symptoms may be followed by dysphonia, dysarthria, dysphagia, and peripheral muscle weakness. If illness is severe, respiratory muscles are involved, leading to ventilatory failure and death unless supportive care is provided. Patients have required ventilatory support for up to 7 months before the return of muscular function, although a 2- to 8-week duration of ventilatory support is more common.[77] Death occurs in 5–10% of cases of food-

borne botulism; early deaths result from a failure to recognize the severity of disease or from pulmonary or systemic infections, whereas deaths after 2 weeks are from the complications of long-term mechanical ventilatory management or respiratory malfunction.[77] An example of how a rapid response to a public health emergency can prevent deaths can be seen in a large foodborne outbreak in Thailand in 2006, in which no deaths occurred among the 209 patients affected. Early detection, prompt administration of antitoxin, supportive care of patients, and collaboration of public health resources in Thailand and globally contributed to the success of the response efforts to this public health emergency.[133]

Perhaps because infants are not able to complain about the early effects of botulinum intoxication, the neurological dysfunction associated with infant botulism often seems to develop suddenly. The major manifestations are poor feeding, diminished suckling and crying ability, neck and peripheral weakness (the infants are often admitted as "floppy babies"), and ventilatory failure.[80,87,120] Constipation is also often seen in infants with botulism and, in some, has preceded by many days the onset of neurological abnormalities. Loss of facial expression, extraocular muscle paralysis, dilated pupils, and depression of deep tendon reflexes have been reported more frequently with type B than with type A infant botulism.[120] Treatment with aminoglycoside antimicrobial agents may potentiate neuromuscular weakness in infant botulism[133] and has been associated with an increased likelihood of needing mechanical ventilation.[80,120] The median length of hospital stay in cases of infant botulism cases treated with human immunoglobulin is 2.6 weeks (range, 2.0–3.3 weeks).[134] Fewer than 2% of reported cases of infant botulism result in death.

8.2. Diagnosis

Botulism is probably substantially underdiagnosed. The diagnosis is not difficult when it is strongly suspected, as in the setting of a large outbreak. However, since cases of botulism most often occur singly, the diagnosis may pose a more perplexing problem. Findings from many outbreaks have suggested that early cases are commonly misdiagnosed and may be diagnosed only retrospectively after death, after the subsequent clustering of cases of botulism-like illness finally alerts public health personnel to the occurrence of an outbreak of botulism[5,6,135]; other cases are undoubtedly missed entirely. Entire outbreaks may even go undetected despite severe illness in patients; for example, one outbreak was recognized retrospectively only after a second cluster of cases occurred due to the same vehicle.[7] In this particular outbreak, two sisters diagnosed with botulism led to the identification of 36 unrecognized cases of type B botulism in the preceding 6 weeks.

Botulism should be suspected in any adult with a history of gastrointestinal, autonomic (e.g., dry mouth, difficulty focusing), and cranial nerve (diplopia, dysarthria, dysphagia) dysfunction or in any infant with poor feeding, diminished sucking and crying ability, neck and peripheral muscle weakness, and/or ventilatory distress.[8,136] The demonstration of bilateral cranial nerve findings and the documentation of neurological progression (peripheral muscle weakness, ventilatory compromise) increase the level of suspicion. The diagnosis is even more likely if an adult patient has recently eaten home-canned foods or if family members are similarly ill, or both. If the typical clinical syndrome is present and no food item can be pinpointed as a means of transmission, a contaminated wound should be sought. If the typical syndrome is seen and a wound is identified, the wound should be explored and, in addition to routine cultures, specimens should be taken for anaerobic culture and toxicity testing even if the wound appears clean.

The differential diagnosis includes myasthenia gravis, stroke, Guillain–Barré syndrome, bacterial and chemical food poisoning, tick paralysis, chemical intoxication (e.g., from carbon monoxide, barium carbonate, methyl chloride, methyl alcohol, organic phosphorus compound, or atropine), mushroom poisoning, medication reactions (e.g., from antibiotics such as neomycin, streptomycin, kanamycin, or gentamicin), poliomyelitis, diphtheria, and psychiatric illness. In infant botulism, sepsis (especially meningitis), electrolyte–mineral imbalance, metabolic encephalopathy, Reye's syndrome, Werdnig–Hoffman disease, congenital myopathy, and Leigh's disease should also be considered.

Routine laboratory studies are not helpful in confirming the clinical suspicion of botulism. Serum electrolytes, renal and liver function tests, complete blood tests, urinalysis, and electrocardiograms will all be normal unless secondary complications occur. A normal cerebrospinal fluid (CSF) examination helps differentiate botulism from Guillain–Barré syndrome, except protein may be normal early in the course of Guillain–Barré and a slightly elevated CSF protein level is occasionally seen with botulism.[77] Normal neuroradiological studies, such as computed tomographic scans or magnetic resonance imaging, help to rule out stroke, another condition commonly confused with botulism.[7,135] Although, early in the course of a potential cerebral vascular event, neurological studies may be normal.

Electromyography (EMG) may be helpful in distinguishing botulism from myasthenia gravis and Guillain–Barré syndrome, diseases that botulism often mimics closely. A characteristic EMG pattern observed in adult patients with botulism has been well described[71,137,138] and includes a low-amplitude response to a single stimulus, a decremental trend in amplitude of the elicited action potentials

to repetitive low-frequency stimulation (2–5 Hz), and an incremental trend (facilitation) to rapid repetitive stimulation (20–50 Hz). However, rapid repetitive stimulation is much more sensitive and specific for botulism than low-frequency stimulation.[7] EMGs should be performed on clinically involved muscles; positive results may be obtained from only one muscle even though many are weak.

The most prominent EMG finding is infant botulism is the same as that in adults: an incremental response to rapid repetitive stimulation.[139] However, another EMG pattern has been described as characteristic of infant botulism.[140] This is the pattern of "brief duration, small amplitude, overly abundant (for the amount of power being exerted)" motor unit action potentials, termed "BSAP" (brief-duration, small-amplitude, overly-abundant motor-unit action potentials) by Engel.[141] Polyphasicity may also be part of this pattern. It is not unusual to find either a BAP pattern (if the motor unit potentials are only brief) or a SAP pattern (if the motor unit potentials are only small) in patients who have typical BSAP findings in other parts of a muscle or in other muscles.

Detection of toxin in serum provides laboratory confirmation of a case of botulism (other than infant). Serum from infants is rarely positive and is difficult to obtain from those most at risk due to their young age. In addition to serum testing, culture of tissues debrided from a wound may facilitate laboratory confirmation of wound botulism cases. Toxin detection in stool specimens or epidemiologically incriminated foods and/or toxin production in culture of stool can be used to confirm a case of foodborne botulism.[8,9] Cultures were positive for 51% of stool specimens and toxin testing was positive for 37% of sera and 23% of stool specimens collected from 309 persons with clinically diagnosed botulism reported to CDC from 1975 to 1988; at least one laboratory test was positive for 65% of patients.[40] Collecting stool and sera samples early during the course of illness increases the likelihood of obtaining positive results. However, in any given situation, these tests may not be helpful; large outbreaks have occurred in which none[142] or a very low percentage[149] of specimens yielded positive results. In addition, laboratory results may not be reported until many hours or days after the specimens are received. The administration of antitoxin is the only specific therapy available for botulism, and evidence suggests that it is effective only if given very early in the course of neurological dysfunction.[123] Hence, the diagnosis of this illness cannot await the results of studies that may be long delayed and may be confirmatory only in some cases. The diagnosis should be made on the basis of the history and physical findings.

9. Prevention, Control, and Treatment

9.1. Prevention and Control

The prevention of foodborne botulism depends on destroying all *C. botulinum* spores in food as it is preserved or creating a milieu in the preserved foods that will not allow the growth of any organisms that survive preservation procedures. This requires careful home canning and commercial canning techniques. Several private and government agencies (e.g., the US Department of Agriculture) provide information on the proper methods of home canning. Although the heat resistance of *C. botulinum* spores is quite variable, cooking at 121°C (250°F) or higher is usually sufficient to destroy all spores.[25–27] These temperatures can be achieved only in a pressure cooker. Boiling alone may kill competitive organisms and create an anaerobic environment highly favorable to the growth of *C. botulinum*. Boiling is sufficient for fruits and certain vegetables, especially those with added sugar, because their high sugar content will not support the growth of *C. botulinum*.[24] Commercial chopped garlic bottled under oil has caused two outbreaks of botulism.[7,114] As a result, this food must now be acidified with phosphoric acid. Previously, tomatoes were thought to be an extremely low-risk food because of their acidity. Cases of botulism, however, have been caused by contaminated foods that contained tomatoes (such as spaghetti sauce) and by tomato juice.[76] These cases have been attributed to the low-acidity tomatoes that are now being bred for increased "sweetness." Adequate refrigeration alone may be the only control method in the absence of other factors that prevent the germination of *C. botulinum* spores and toxin production in some products, as seen in an outbreak traced to carrot juice, in which the product was not intended to be re-heated before consumption.[65]

Home-canned foods that are contaminated with proteolytic *C. botulinum* organisms or concurrently contaminated with other anaerobic or aerobic organisms will spoil. Foods that look or smell spoiled should not be tasted. Foods contaminated by nonproteolytic strains of *C. botulinum* (and sometimes proteolytic strains as well) may not appear spoiled. Nonproteolytic strains, including type E, may continue to grow even at 3.3°C with little competition from other spoilage bacteria. Food items suspected of having transmitted botulism should be carefully sealed and marked and then be refrigerated and saved for culture and toxin testing. Although *C. botulinum* spores are resistant to heat, botulinum toxins are heat-labile and are readily destroyed by boiling. Thorough boiling of home-canned foods is an added safeguard against botulism.

Commercial canners use a variety of methods to prevent the growth of *C. botulinum*. Commercial canners routinely heat foods to 120°C for 3 min, and often acidify high-risk, low-acid foods such as peppers to inhibit the growth of *C. botulinum*. Semipreserved meat products (e.g., hot dogs and luncheon meats) have nitrites added for similar reasons. Systems for killing spores in foods by radiation are also under investigation. *C. botulinum* is a gas-producing organism, and its growth inside a can may produce enough gas to make the can bulge or swell. More common causes of bulging include overpacking by the manufacturer, gas caused by interaction of the contents and the metal container, or contamination by some other organisms due to a fractured seal. Nevertheless, swollen, bulging cans or cans with spoiled contents should not be consumed and should be reported to local health authorities or to the US Food and Drug Administration (FDA).

Physicians also have an important role in the control of botulism. All suspect cases of foodborne botulism should be reported immediately to local or state health authorities or directly to CDC in Atlanta (telephone 770-488-7100); CDC can assist with clinical consultation, laboratory testing, and antitoxin release. It is important that this be done quickly and efficiently, especially if the suspected vehicle is a commercial product. If the diagnosis is suspected, a search for other cases (initially by identifying persons who shared the implicated food) should be immediately undertaken.

Because the mechanism of transmission for infant botulism has not been totally defined, few control measures are available. Controlled epidemiological studies will be required to develop the necessary data. Since honey is the one identified source of *C. botulinum* spores for susceptible infants and since it is not essential for good infant nutrition, it is recommended that honey not be fed to infants under age 1 year.[80] The prevention of wound botulism depends on the thorough cleansing and debridement of wounds, especially those of any depth or that are contaminated by soil. Wound botulism may be prevented by avoiding the use of black-tar heroin.

Botulinum toxoid, as an investigational new drug (IND) has limited availability.[145] However, because of the rarity of botulism in the general population and the side effects of immunization, toxoid administration is recommended only for laboratory personnel working directly with the organism and the toxin. The toxoid is available from CDC Drug Service (404-639-3670).

9.2. Treatment

The mainstays of treatment of foodborne and wound botulism are as follows: (1) administration of botulinum antitoxin in an attempt to prevent neurological progression of a moderate, slowly progressive illness or to shorten the duration of ventilatory failure in those with a severe, rapidly progressive illness; (2) careful monitoring of respiratory vital capacity, aggressive respiratory care, and mechanical ventilation of needed for those with ventilatory insufficiency; and (3) meticulous and intensive care for the duration of the often prolonged paralytic illness.

Antitoxin therapy is more effective if undertaken early in the course of illness and may reduce the duration of mechanical ventilation shorten the course of illness, and increase the chance of survival.[45,123,146] This is not surprising when one considers that equine antitoxin neutralizes only toxin molecules yet unbound to nerve endings.[126] Most persons (more than 80%) with adult botulism in the United States are treated with equine antitoxin. Administration of one vial of bivalent (types A and B) and one vial of type E botulism antitoxin by the intravenous route results in serum levels of type A, B, and E antibodies capable of neutralizing serum toxin concentrations manyfold in excess of those reported for botulism patients. Therefore, administration of one vial of antitoxin intravenously is recommended and antitoxin need not be repeated, since the circulating antitoxins have a half-life of 5–8 days.[147] However, treatment is not without risk as approximately 9.0% of persons treated experience hypersensitivity reactions, although these data were from the period when more than one vial was given and it is possible that the percentage of persons experiencing hypersensitivity reactions is lower given administration of one vial.[148] It is therefore extremely important that physicians recognize botulism as early in its course as possible, and yet not mistake other neurological syndromes for botulism. CDC has a 24/7 consultancy and antitoxin release service for physicians through state health officials and can be contacted by telephone, 770-488-7100. A heptavalent (types A, B, C, D, E, F, and G) botulinum antitoxin product is currently not licensed in the United States, but would be provided by CDC to treat patients in an emergency situation or those with unusual suspected types C, D, E, F, or G botulism under a treatment investigational new drug (IND) application. In the future, this heptavalent botulinum antitoxin product may become licensed in the United States and in the meantime may be utilized if existing botulinum antitoxin products are unavailable.

For infant botulism, treatment with antibiotics is not indicated as aminoglycosides potentiate the paralytic effects of botulinum toxin. Treatment of infant botulism with the drug, human botulism immune globulin intravenous (BIG-IV, sold under the name of BabyBIG), has been found to be safe and effective in decreasing length of hospital stay,

hospital charges per patient, duration of intensive care unit stay, duration of mechanical ventilation, and duration of tube or intravenous feeding.[127,142] In a 5-year randomized, double-blinded placebo-control trial of BIG-IV in California, patients treated with BIG-IV had significantly shorter length of hospital stay (half), ICU stay, duration of mechanical ventilation, and tube or IV feeding compared to controls. Hospital charges per patient was on average 88,600 US dollars less for patients treated with BIG-IV compared to controls. The number of serious adverse events in patients treated with BIG-IV did not differ significantly with controls. The main adverse event that may be attributed to BIG-IV is erythematous rash.[127,142] BIG-IV was licensed by the FDA following the 5-year clinical study and a 6-year open-label study nationwide. BIG-IV is sold under the name of BabyBIG by the California Department of Health Services' Infant Botulism Treatment and Prevention Program and can be obtained by calling 510-231-7600 or visiting http://www.infantbotulism.org.

10. Bioterrorism

Botulinum neurotoxins are on CDC's list of select agents and toxins (http://www.cdc.gov/od/sap/docs/salist.pdf) as a Category A agent. Category A agents are the highest priority agents that pose a risk to national security because they can be easily disseminated or transmitted person-to-person, cause high mortality, might cause public panic and social disruption, and require special action for public health preparedness.[150] Historically, attempts have been made to use botulinum toxin as a bioterror weapon.[151,152] To date, botulism caused by inhalation of aerosolized toxin has only occurred in laboratory workers. These patients had similar neurological symptoms seen in foodborne botulism and recovered within 2 weeks following inhalational exposure. The course of illness suggested for inhalational botulism is irritant upper airway prodrome with initial exposure followed by a variable onset of different degree of paralysis in exposed patients.[157] Because of its potency, small amounts of botulinum toxin have the potential of causing widespread and catastrophic illness. The severity of illness and potential for intentional release of botulinum toxin highlight the need for clinicians to recognize the symptoms of botulism and for diligent surveillance by federal, state and local health departments. Every suspicious case of botulism, whether naturally occurring or suspected bioterrorism, should be reported to CDC's Emergency Operations Center (770-488-7100).

11. Unresolved Problems

Much is now known concerning the epidemiological and clinical aspects of adult forms of botulism. The most prominent persisting problem may be the low index of suspicion for botulism among clinicians who are unlikely to diagnose even one case in a career. The development of laboratory tests that are equally as sensitive and specific as the mouse bioassay, but more rapid, would be helpful in confirming illness and potentially could help support treatment recommendations. The development of an antitoxin derived from human serum or by monoclonal antibodies could provide an approach to antitoxin therapy that is safer (because less likely to cause hypersensitivity reactions than equine antitoxin) and perhaps less expensive. Although the clinical spectrum of illness and descriptive epidemiology of infant botulism have been well characterized in the few years since its discovery, specific risk factors and vehicles of transmission remain obscure for most cases. Controlled epidemiological studies are needed to further clarify ways of preventing this important source of childhood morbidity. The demonstration in some adults of a pathogenic mechanism similar to that of infant botulism blurs somewhat the distinction between adult and infant forms of the disease, and may initiate reconsideration of pathogenesis and treatment in both groups. Finally, increasing identification of *Clostridia* other than *C. botulinum*, in particular the rise in the occurrence of botulism due to *C. baratii* type F, has further aggravated the complexity of laboratory investigations of botulism.

All cases of suspect foodborne and wound botulism and adult botulism from intestinal colonization should be reported to CDC through state health departments. CDC can assist with clinical consultation, laboratory testing, antitoxin release, and epidemiologic investigation to identify vehicles and get implicated products removed from stores and homes quickly.

CHAPTER 8

Brucellosis

Edward J. Young

1. Introduction

Brucellosis is an infectious disease of animals (zoonosis) that is transmittable to humans. Humans are always accidental hosts, playing no role in maintaining the disease in nature. In the United States, brucellosis has been largely controlled as a result of the Federal/State Cooperative Bovine Brucellosis Eradication Program.[1] Consequently, reports of human brucellosis have declined to about 100 cases per year, with most originating in areas where the disease remains enzootic.[2]

Although there is a high degree of relatedness among *Brucella* species, the genus is traditionally classified into six nomen species based on their major animal hosts: *Brucella abortus* (cattle), *B. melitensis* (goats and sheep), *B. suis* (swine), *B. canis* (dogs), *B. ovis* (sheep), and *B. neotomae* (desert wood rats). To this list must be added recent brucella isolates from marine mammals tentatively termed *B. maris*. *Brucella ovis* and *B. neotomae* are not human pathogens, and the potential for marine mammal strains to cause human infection remains uncertain.[3]

Animals are the only source of brucellosis and there are no known vectors. Brucellosis in humans is a protean disease characterized by a plethora of nonspecific complaints, such as fatigue, anorexia, weight loss, malaise, body aches, and depression. Aside from fever, and occasionally hepatosplenomegaly, there can be a paucity of abnormal physical findings.

Edward J. Young • Medical Service, Veterans Affairs Medical Center; Departments of Medicine, Microbiology, and Immunology, Baylor college of Medicine, Houston, Texas 77030, USA.

2. Historical Background

It is likely that brucellosis has existed since man first domesticated animals; however, Jeffery Allen Marston, a Royal Army Medical Corps (RAMC) surgeon, is credited with the first accurate description of the disease among troops invalided to Malta during the Crimean War.[4] David Bruce, another RAMC surgeon, researched Malta fever among military personnel at the Station Hospital in Valletta, and in 1887 isolated a gram-negative coccobacillus from the spleens of seven fatal cases. In 1897, M.L. Hughes, RAMC, published a classic monograph reviewing the clinical and pathological features of the disease and suggesting the name undulant fever.[5] The same year, Wright and Semple successfully applied the method of serum agglutination for diagnosis, enabling clinicians to differentiate brucellosis from typhoid, malaria, and other febrile illnesses.

In 1904, the Mediterranean Fever Commission was established, and between 1904 and 1907, seven *reports* were published detailing the bacteriology, epidemiology, and pathology of brucellosis.[6] In 1905, Themistocles Zammit, a civilian member of the Commission, identified Maltese goat as the animal host of brucellosis and fresh goat's milk as the vehicle of transmission from animals to human.[7] The causative organism was named *Micrococcus melitensis*, and it was found to be widespread in goat populations around the Mediterranean and elsewhere in Europe.[8] When unboiled goat's milk was eliminated from the diets of the military, the number of cases of human brucellosis declined precipitously.

In 1895, the Danish physician and veterinarian Bernhard Bang isolated an organism he termed *Bacterium abortus* from placental tissue of cattle suffering contagious abortions.[9] This disease was believed to be different from that producing abortions in goats and sheep; therefore, no human infection was ascribed to the known presence of Bang's bacillus in the milk of many herds.[10] In 1918,

Alice Evans published data showing the antigenic relatedness between *B. melitensis*, the causative agent of Malta fever, and *B. abortus*, the agent of contagious abortion in cattle.[11] Subsequently, the genus was named *Brucella* to honor Bruce. Human infection with *B. abortus* was documented in 1924 by Orpen[12] in Great Britain, although studies by Morales-Otero using volunteers in Puerto Rico showed that *B. abortus* was more easily transmitted via direct inoculation through breaks in the skin than by ingestion of milk.[13]

In 1914 Jacob Traum isolated *B. suis* from an aborted swine fetus,[14] although the organism may well have been recovered as early as 1909 by Hutyra and Marek in Hungary.[15] *Brucella suis* has a more limited geographic distribution than either *B. abortus* or *B. melitensis*, and its biovars have different natural hosts. Biovars 1, 2, and 3 cause infection in swine, whereas, biovar 4 is limited to reindeer and caribou populations of the sub-Arctic regions of Alaska, Canada, and Siberia. Biovar 5 is a rodent pathogen and human infections have been limited to laboratory accidents.[16] Human infection with *B. suis* biovars 1–3 is notably associated with certain occupational groups, including meat inspectors, butchers, and abattoir workers. Infection with *B. suis* is also a risk for feral swine hunters, since the disease is widespread in these animals and their popularity as game animals increases. During butchering, hunters are exposed to blood and body fluids and the risk of contracting the disease is extremely high, since *B. suis* is shed continuously in urine and seminal discharges, not just at the time of abortion or parturition.[17]

Brucella canis was first reported as the cause of contagious abortion among kennel-bred dogs in 1964 by Carmichael and Bruner,[18] and human infection was documented in 1972 by Swenson and colleagues.[19] Serological studies of dogs of different breeds indicate that *B. canis* is widespread throughout the world.[20] The incidence of *B. canis* infections in humans is not known with certainty. The few cases reported in the literature indicate close contact with infected dogs or their secretions or laboratory-acquired infections.[21]

In 1994, Ross and colleagues isolated brucellae from the carcasses of marine mammals that were stranded off the coast of Scotland,[22] and Ewalt and colleagues recovered a *Brucella* species from the aborted fetus of a bottlenose dolphin in California.[23] Subsequently, several *Brucella* strains were isolated from a wide variety of marine mammal species throughout the world.[24] These strains are distinct from previously recognized nomen speciesand can be divided into two groups based on cultural characteristics and host species. The group was tentatively called *B. maris*, with putative biovars *B. cetaceae* and *B. pinnepediae* from their natural host species.[2,25]

3. Methodology

3.1. Sources of Data

In the United States, human brucellosis is a notifiable disease and morbidity and mortality data are reported weekly to the Centers for Disease Control and Prevention (CDC)[26]; however, there is evidence to suggest that underreporting remains a problem. For example, a study by the Texas Department of Health in 1990–1991 indicated that less than one half of the cases of human brucellosis diagnosed were actually reported.[27] Worldwide, information on human brucellosis is tabulated by the World Health Organization (WHO); however, since the disease is not reportable in many countries the reliability of these data is questionable. Moreover, in many countries where the disease is enzootic, facilities for diagnosis and mechanisms for reporting are limited, so numbers of cases may be under- or overestimated.

3.2. Surveys

Serological surveys for brucellosis in cattle and swine are routinely performed under the guidelines of the Brucellosis Eradication Program and states are rated according to the numbers of reactor animals in test herds and at sale barns. Rules and regulations concerning the control and eradication of the disease in animals are published periodically in the *Federal Register*.

3.3. Laboratory Diagnosis

3.3.1. Isolation and Identification of the Organism. A definitive diagnosis of is made by recovering *Brucella* from blood, bone marrow, or other tissues. Since brucellae are facultative intracellular pathogens that rapidly localize within organs of the reticuloendothelial system, cultures of bone marrow may have a higher yield than blood.[28] A variety of bacteriological methods have been used including the broth/agar technique of Castañeda; however, automated systems such as BACTEC have reduced the time of isolation from weeks to days.[29] Isolation rates for brucella bacteremia vary from 15 to 70%, in part, relating to the methods used and the intensity of the search.[30] Because brucellae grow slowly in vitro, it is necessary to maintain cultures for at least 4 weeks before declaring them negative. Polymerase chain reaction (PCR)-based assays have been developed for the identification of *Brucella* species and have found use in veterinary diagnostics.[31] Although a variety of primers have been studied, to date, PCR has found only limited use in the diagnosis of human brucellosis.[32] Nevertheless,

advances in PCR technology, such as rapid cycle real-time PCR and combinations of PCR with restriction enzymes, have made the technique more rapid and more specific.[33] Clinical laboratories utilizing automated rapid identification systems should ensure that they contain database profiles for *Brucella*, since misidentifications as *Moraxella* sp. or *Haemophilus* sp. have been reported.[34] Brucellosis has long been recognized to be a risk for laboratory personnel handling clinical material[35–37] and the use of biohazard precautions is mandatory.

3.3.2. Serological and Immunological Tests. In the absence of bacteriologic confirmation, the diagnosis of brucellosis depends on the demonstration of high or rising titers of specific antibodies in the serum. During the course of infection with *Brucella* sp. antibodies of all major immunoglobulin classes (IgA, IgM, and IgG) are generated against both cell wall and cytoplasmic antigens. Most serological tests for Brucella antibodies employ smooth lipopolysaccharide (S-LPS), the immunodominant cell wall antigen that is shared by all smooth species, *B. abortus*, *B. melitensis*, and *B. suis*. Because *B. canis* is a naturally rough species, a homospecific antigen is required to diagnose infection with this organism.[20,21,38]

Since it was first developed in 1897, serum agglutination has been the mainstay of brucella serodiagnostics.[39] The antigen preparation is standardized and the results can be expressed in international units that can be correlated well with clinical signs of infection. The problem of defining a serum agglutination titer (SAT) indicative of active infection remains a problem; however, most authorities consider $\geq$1:160 (200 IU) to be diagnostic when combined with compatible historical and clinical findings.[40] Qualifications of the SAT include cross-reactions with antibodies to other organisms, including *Francisella tularensis, Vibrio cholerae,* and *Yersinia enterocolitica* serotype O:9, and a prozone phenomenon with high levels of antibody. These problems can be overcome by routinely diluting serum $>$1:320. On rare occasions, the serum of a patient with bacteriologically confirmed brucellosis will fail to agglutinate owing to the presence of a "blocking" substance. So-called blocking antibodies are generally IgG or IgA isotype and can be detected using Coombs test.[41]

The SAT measures the total quantity of *Brucella* agglutinins, but it does not distinguish between IgM and IgG isotypes. One method to do this is based on the action of mercaptans, such as 2-mercaptoethanol (2ME) or dithiothreitol (DTT) to disrupt the disulfide bonds of the IgM pentamer and negate its ability to agglutinate.[42] The SAT, using phosphate-buffered saline (PBS) as the serum diluent, is performed in parallel with the SAT using PBS containing 0.05 M 2ME (or DTT). Any decline in titer that is observed between the two tests represents the content of 2ME-susceptible (IgM) antibodies.[43] The validity of this interpretation has recently been challenged by studies showing that in selected cases, both IgA and IgG can interfere with the action of mercaptans.[44]

Perhaps the most significant advance in *Brucella* serologic tests has been the development of immunoassays, such as the enzyme-linked immunosorbent assay (ELISA).[45,46] A variety of *Brucella* antigens have been studied, including whole cells, S-LPS, outer membrane proteins, and cytoplasmic proteins.[47] The measurement of specific IgA, IgM, and IgG isotypes is the most sensitive method available. A decline in IgG antibodies is associated with a good clinical response to therapy, whereas persistence of such antibodies is associated with chronic infection or relapse.[48]

Among rapid diagnostic tests for brucellosis, rose bengal agglutination is a qualitative plate assay that is useful for screening purposes; however, positive reactions must be confirmed with a more sensitive quantitative method. A new dipstick assay for detecting IgM antibodies to S-LPS is simple to perform, can be applied to field conditions, and shows a good correlation with other methods.[49] Multiple antigen tests, such as the febrile agglutinin screen, should not be used to diagnose brucellosis since they lack specificity and are difficult to interpret.[50]

Since brucellae are facultative intracellular pathogens, cell-mediated immunity appears to be more important in recovery than humoral factors.[51] A variety of tests are available to test cellular immunity, and while useful for understanding the pathogenesis of infection, none are useful for diagnostic purposes. In addition, skin tests are not recommended for diagnostic purposes because there are no standardized preparations, they have the potential to induce a humoral response, and they do not identify patients with active infection.[52]

4. Biological Characteristics of the Organism

Brucellae are small gram-negative coccobacilli measuring about 0.6 μm long by 0.5–0.8 μm wide. They lack a capsule, endospores, flagellae, or native plasmids. The outer cell membrane resembles other gram-negative bacilli with a dominant lipopolysaccharide (LPS) component. Most strains do not have an obligatory requirement for carbohydrates; however, the growth of *B. abortus* strains is enhanced by erythritol, which is used in preference to glucose as an energy source. Metabolism is oxidative and all strains are aerobic, although some require an atmosphere of 5–10% CO_2 for primary isolation.[53] All brucellae are oxidase and catalase

positive. Differentiation between species and biovars is based on biochemical reactions, growth on media containing dyes, agglutination by specific antisera, and susceptibility to lysis by specific bacteriophages (Table 1). Recently, analysis of fragment lengths of DNA cut by various restriction enzymes has been used to differentiate *Brucella* sp.[54]

Brucella spp. are alpha-*Proteobacteria* phylogenetically related to plant pathogens and symbionts such as *Rhizobium* and *Agrobacterium*, intracellular animal parasites such as *Bartonella* and *Rickettsia*, and to opportunistic and free-living bacteria such as *Ochrobactrum* and *Caulobacter*.[55] Originally the genus was classified into six species (*B. melitensis, B. abortus, B. suis, B. neotomae, B. ovis*, and *B. canis*) and subdivided into biovars or biotypes, based primarily on natural hosts. When the results of DNA–DNA hybridization studies showed a high degree of relatedness among *Brucella* sp., it was proposed that the genus be reclassified as a single species (*B. melitensis*) with the other nomen species classified as biovars.[55,56] However, such a single-species organization does not accurately reflect the observed differences in pathogenicity, host preferences, and evolutionary history,[57] and clinicians prefer the nomen species designation for epidemiological considerations.

Most *Brucella* sp. contain two circular chromosomes of approximately 2.1 and 1.15 Mb, except *B. suis* biovar 3 which has a single chromosome of 3.1 Mb.[58] Sequencing of the genomes of *B. suis*,[59] *B. melitensis*,[60] and *B. abortus*[61] confirmed the relatedness of the species and the presence of a small number of unique genes located on chromosomal regions called genetic islands.[62] It has been suggested that the low rate of genetic exchange among intracellular bacteria such as brucella can be attributed to their isolated location within cells of the host. Despite rapid advances in our knowledge of the genetics of brucellae, the factors relating to virulence and host specificity remain elusive.[63]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

In the United States, the incidence of human brucellosis decreased after World War II from more than 6,000 cases per year (4.5 cases per 100,000 population) in 1948 to approximately 100 cases per year (0.05 cases per 100,000 population) in 2006 (Figure 1). This decline can be attributed to efforts to eliminate brucellosis in animals and laws requiring pasteurization of milk for human consumption. The situation worldwide is less encouraging, and infection predominantly caused by *B. melitensis* remains at epidemic levels in some areas, notably the Middle East. For example, in 2005, the Ministry of Health of Iran reported 25,755 cases of human brucellosis for an incidence of 38/100,000 population.[64] To some extent, this represents better awareness of the problem, better surveillance, and case identification.[65]

5.1.1. High-Risk Categories. Traditionally, brucellosis has been an occupational hazard for farmers, ranchers, veterinarians, abattoir workers, and laboratory personnel. In recent years, the epidemiology of brucellosis has changed in some areas. For example, in Texas, between 1977 and 1986, the majority of patients with brucellosis were Caucasian men with documented exposure to cattle or swine in the course of their occupations. In contrast, between 1982 and 1986, the preponderance of cases occurred in Hispanics of both sexes and the source of infection was unpasteurized goat's milk cheeses originating in Mexico.[66] The shift from occupationally acquired brucellosis to foodborne transmission has also been reported in California.[67,68] Tourists visiting countries where brucellosis is enzootic are also at risk especially if they partake of local food "delicacies" such as goat's milk cheese or candy.[69] Moreover, with the speed of international travel, the symptoms of brucellosis may not become apparent until the traveler returns to the United States.[70]

Brucellosis is a recognized hazard for laboratory personnel working with clinical specimens containing brucellae.[35–37] Although infection with any species of *Brucella* can occur from laboratory accidents,[71] in view of its greater virulence, *B. melitensis* accounts for the majority of cases.[72,73] Laboratory personnel with exposure to infectious aerosols may benefit from antibiotic prophylaxis, whereas lesser exposure can be followed with antibody titers.[74] Although brucellosis is not generally considered a nosocomial pathogen, hospital personnel should employ bloodborne pathogen precautions when caring for patients with brucellosis.[75]

5.2. Epidemic Behavior and Contagiousness

Foodborne outbreaks caused by *B. melitensis* have been reported among individuals ingesting unpasteurized goat's milk cheeses.[76] Such outbreaks often involve entire families, including children, without direct contact with animals. In contrast, infection with *B. abortus* is more often sporadic and usually involves direct contact with diseased animals or their parts. Generally, infection caused by *B. suis* has occurred in abattoirs where infected swine are slaughtered.[77–79] In recent years, with the increasing popularity of hunting feral swine, human infection with *B. suis* has been traced to the killing and dressing of these animals in the Southern United States and elsewhere.[80,81]

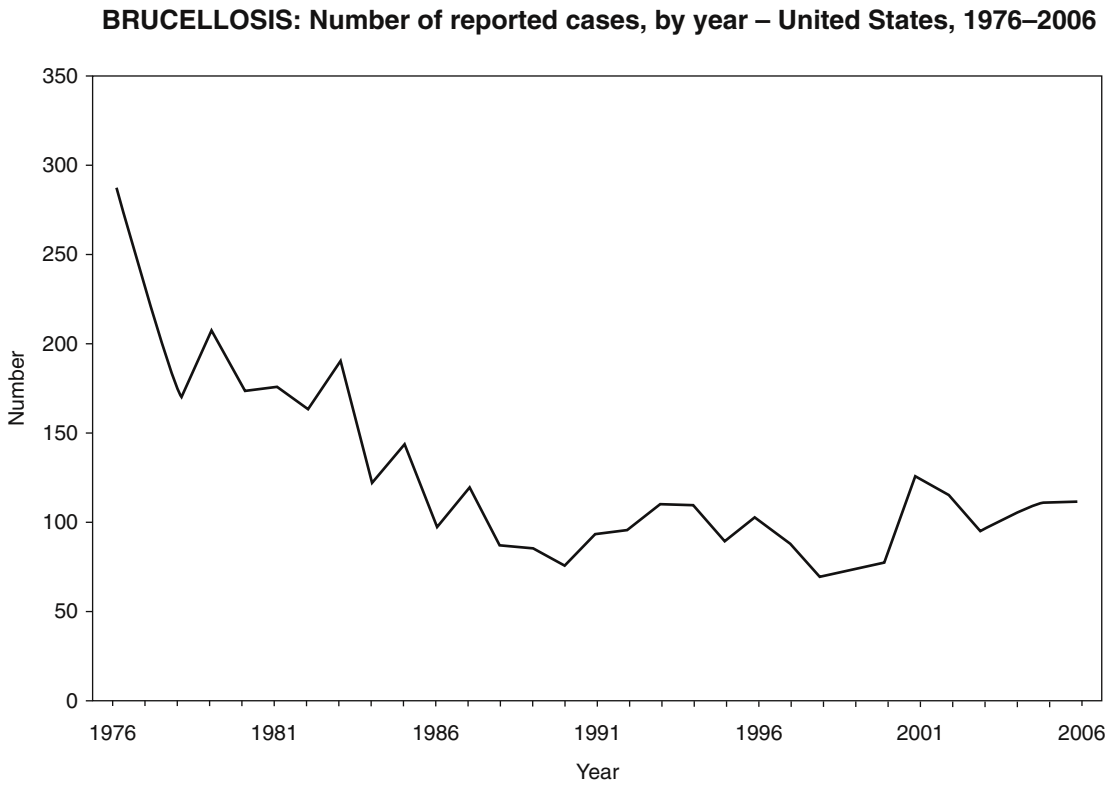

Figure 1. The incidence of brucellosis has remained stable in recent years, reflecting an ongoing risk for infection with *Brucella melitensis* and *B. abortus* acquired through exposure to unpasteurized milk products in countries with endemic brucellosis in sheep, goats, and cattle and *B. suis* acquired through contact with feral swine in the United States.

Brucellosis in humans is not as contagious as it is in animals and human-to-human transmission is rare. Nevertheless, brucellae have been isolated from banked spermatozoa[82] and cases of presumed venereal transmission have been reported.[83,84] A case of *B. melitensis* isolated from human milk also suggests that women with brucellosis should avoid breast-feeding until the disease is treated.[85] Interestingly, unlike other zoonoses, patients with human immunodeficiency virus (HIV) infection do not appear to be at greater risk of brucellosis[86] nor do they have a more severe course when infected.[87]

5.3. Geographic Distribution

Brucellosis occurs worldwide, but is especially prevalent in the Mediterranean basin, the Arabian Peninsula, the Indian subcontinent, and in parts of Mexico, Central and South America. It has been long known that the incidence of human brucellosis is a reflection of the prevalence of the disease in animals. This is illustrated by the concentration of human cases in states that border Mexico where the disease remains enzootic in goats and where goat's milk products cross the border as a traditional food item. Brucellosis in the US region bordering Mexico occurs at a rate eight times higher than elsewhere in the country.[88] The influence of war and economic hardship on the incidence of brucellosis is illustrated by epidemic proportions of the disease in Iran, Iraq, Kuwait, Afghanistan, and states of the former Soviet Union. The situation in sub-Saharan Africa is complicated by a general lack of facilities for diagnosing and reporting cases of brucellosis. A current assessment of worldwide brucellosis has been reported by Pappas and colleagues.[65]

5.4. Temporal Distribution

Although brucellosis can be contracted at any time of the year, seasonal trends have been reported. In a series from California the onset of symptoms occurred between February and May in about one half of bacteriologically confirmed cases.[67] A similar distribution was reported in cases from Texas.[66] In Saudi Arabia, cases were noted to peak in the spring, when many people camp in the desert and exposure

to animals increases.[89] In the Southern Hemisphere where the seasons are reversed, the disease occurs primarily in the fall. Outbreaks of human brucellosis in Peru between 1939 and 1967 coincided with epizootics in goats. Years with abundant rainfall were followed by increased animal parturition, more susceptible goats, and increased milk and cheese production.[90]

5.5. Age and Sex Distribution

Brucellosis can afflict persons of all ages; however, occupation-associated disease reflects the workforce, and men aged between 20 and 60 years have traditionally been at greatest risk.[91] In countries where *B. melitensis* is enzootic, including Mexico and Saudi Arabia, women are more often infected as a result of food exposure.[92] Once considered rare in children, in many areas children less than 15 years of age account for up to 40% of brucellosis cases.[93]

5.6. Brucellosis During Pregnancy

Spontaneous abortion is the principal manifestation of brucellosis in animals and localization of brucellae within the reproductive organs of both sexes is well known. Erythritol is found in the placenta and fetal tissues of pregnant cows and it has been shown to be a growth stimulant for *B. abortus*.[94] Erythritol is not found in human placental tissues and the role of brucellosis as a cause of abortion in humans was questioned.[95] In a retrospective study from Saudi Arabia, Khan and colleagues reported a 46% incidence of spontaneous abortion and intrauterine death among 92 pregnant women with brucellosis.[96] This figure exceeded the rate of spontaneous abortion among the general population during corresponding trimesters. Moreover, the authors found that early diagnosis and treatment prevented abortion and fetal death.

5.7. Innate Immunity

Although there are no known racial or genetic differences in susceptibility to brucellosis in humans, innate immunity has been demonstrated in a variety of animal species. Cameron and associates first demonstrated genetically determined resistance in swine infected with *B. suis* in the 1940s.[97] Using inbred cattle, Templeton and Adams demonstrated high levels of resistance to *B. abortus* mediated by a gene complex termed Nramp-1 (natural resistance-associated macrophage protein 1) located on the bovine chromosome 2.[98] The Nramp-1 gene is expressed primarily in tissue of the RES, and macrophages from resistant cattle showed an enhanced ability to control intracellular replication of brucellae.[99]

6. Mechanisms and Routes of Infection

Brucella abortus is usually transmitted via direct cutaneous inoculation through minor cuts and abrasions in the unprotected skin. Oral transmission via unpasteurized milk can also occur, but *B. abortus* is less pathogenic than *B. melitensis* by this route.[13] Veterinarians immunizing cattle with *B. abortus* strain 19 are at risk from accidental needle sticks or eye splashes with this live attenuated vaccine.[100] The transmission of *B. melitensis* is predominantly via ingestion of unpasteurized milk or milk products from goats, sheep, and, in some areas of the world, camels. Transmission of *B. suis*, other than biovar 4, is generally associated with the slaughter of swine. Outbreaks in abattoirs occur principally in the kill areas where workers are exposed to aerosols of blood that can enter the respiratory tract or through the conjunctivae of the eyes.[77,78] Hunters of infected feral swine are at risk of direct inoculation of *B. suis* during the act of dressing the kill unless they take precautions to prevent exposure to blood.

6.1. Brucellosis in Wildlife

Although brucellosis occurs mainly in domestic and semi-domestic animals, a variety of wildlife are susceptible including elk, caribou, and bison. The role of wildlife as a source of brucellosis for domestic animals continues to be debated despite evidence that under experimental conditions, bison-to-cattle transmission of *B. abortus* was demonstrated. Similarly the role of brucellae isolated from marine mammal and their potential to cause human disease remains to be fully elucidated.[101]

7. Pathogenesis and Immunity

The incubation period of human brucellosis is variable depending in part on the *Brucella* spp., the route of transmission, the size of the inoculum, and the immune and nutritional status of the host. The majority of patients become symptomatic within 1–4 weeks after infection and the onset is insidious in about one half of the cases. Infection caused by *B. melitensis* or *B. suis* tends to be more severe than *B. abortus* or *B. canis*.[68] Although morbidity is considerable, death occurs in less than 1% of cases.

Normal human serum has limited bactericidal activity against *Brucella* spp. and is greatest against *B. abortus*, moderate against *B. melitensis* and *B. suis*, and undetectable against *B. canis*.[102] Chemotactic factors attract neutrophils

to the site of infection where brucellae opsonized by complement are phagocytized. In vitro studies using neutrophils from normal subjects indicated that *B. abortus* is killed more efficiently than *B. melitensis*.[103] The mechanisms by which brucellae survive within neutrophils are poorly understood; however, virulent strains of *B. abortus* appear to contain a potent superoxide dismutase enzyme and nucleotide substances (adenine and guanosine monophosphate) that inhibit phagolysosome fusion, degranulation, and activation of the myeloperoxidase–halide system.[104] Smooth lipopolysaccharide (S-LPS) appears to play an important role in intracellular survival as smooth organisms survive more efficiently than non-smooth organisms.[105] Organisms that escape killing by neutrophils enter the lymphatics where they localize within organs of the RES. Survival within macrophages is dependent upon specific proteins including stress proteins, such as HtrA, that is also involved in the granulomatous response.[106] Replication of brucellae continues within macrophages until these cells are "activated" by specifically committed T-lymphocytes. CD-4 cells play a role either by activating CD-8 T-cells or by secreting cytokines, especially interferon-γ.[107] Although humoral antibodies appear to play some role in resistance to brucellosis, cell-mediated immunity predominates.[108]

8. Patterns of Host Response

The host response in brucellosis is somewhat dependent upon the *Brucella* spp. and the tissue in which it is viewed. Characteristically, infection with *B. abortus* induces a granulomatous reaction which can be demonstrated in the bone marrow, liver, spleen, and lymph nodes. Granulomas are detected in bone marrow in up to 75% of cases; however, they are often small and have indistinct borders.[109] Occasionally there is an increase in histiocytes showing erythrophagocytosis that may correlate with severe thrombocytopenia.[110]

The liver is the best studied organ and percutaneous liver biopsies from patients infected with *B. abortus* characteristically reveal noncaseating epithelioid granulomas indistinguishable from sarcoidosis.[111] In contrast, infection with *B. melitensis* can produce a spectrum of histologic features including small aggregates of mononuclear cells around necrotic foci, a diffuse mononuclear cell infiltrate resembling viral hepatitis, and occasionally loose granulomas containing histiocytes.[112] Infection caused by *B. suis* characteristically produces suppurative abscesses that can become chronic and can reactivate many years later.[113] Localized infection with either *B. suis* or *B. melitensis* can give rise to so-called hepatosplenic brucellosis.[114,115]

8.1. Clinical Features

The spectrum of human brucellosis ranges from subclinical to chronic. Whether the onset is acute or insidious, it is characterized by a myriad of nonspecific complaints including fever, sweats, weakness, fatigue, headache, arthralgia, and depression. When untreated the fever pattern is undulating, but follows the usual diurnal variations. In contrast, there is often a paucity of abnormal physical findings, notably fever and hepatosplenomegaly. Treatment with appropriate antimicrobial drugs shortens the course of illness and lessens complications. Any organ or system of the body can be involved, but osteoarticular complications are the most frequent occurring in up to 60% of cases in some series.[116] A variety of bone and joint lesions have been reported, but sacroiliitis is reportedly the most common.[117,118]

Other complications of brucellosis can involve respiratory, gastrointestinal, hepatobiliary, genitourinary, cardiovascular, and nervous systems. With treatment most patients recover fully within weeks to months; however, as many as 15% relapse depending on the antimicrobial agents used and the length of therapy. Clinical relapse generally occurs within 3–6 months after stopping therapy and is usually not caused by the emergence of antibiotic-resistant strains.[119] The causes of relapse are multifactorial, but discontinuation of antibiotics before completing a full 6-week course is an important consideration. The majority of patients who relapse can be treated successfully by repeating a full course of the same antibiotics. Rarely chronic infection occurs, during which patients can experience bouts of fever and other symptoms and the titer of IgG antibodies remains elevated. The cause is usually a focus of infection in the tissues that may require surgical intervention and prolonged antibiotics. A minority of patients experience a delayed convalescence during which they complain of prolonged illness, but they can be distinguished from chronic brucellosis by the absence of fever and antibody titers are not elevated.[120]

8.2. Diagnosis

The diagnosis of brucellosis requires a high index of suspicion derived from a history that includes occupation, avocations, exposure to animals, ingestion of high-risk foods, and travel to areas where the disease is prevalent. Routine laboratory tests are generally not helpful, except that the WBC count is often normal or low.[121] Although patients develop cutaneous hypersensitivity to brucella antigens, skin tests are not useful in making the diagnosis. A definitive diagnosis is made by recovering brucellae from blood, bone marrow, or other tissues. In the absence of bacteriologic

confirmation, the diagnosis rests with the demonstration of high or rising titers of specific antibodies in the serum.[40]

9. Control and Prevention

9.1. General Concepts

Despite the availability of effective vaccines to prevent brucellosis in animals, the disease remains enzootic in many countries. What then hampers the control and eradication of this important and widespread zoonosis? In 1993, the International Task Force for Disease Eradication concluded that brucellosis would not be targeted for eradication worldwide because of a "low political will".[122] In part, this reflects the high cost of brucellosis eradication programs, but it also indicates the failure of governments to recognize the public health implications of animal diseases. Epidemiologic studies have shown that the persistence of brucellosis in animals and man's risk of contracting the disease are closely linked to (a) methods of animal husbandry, (b) standards of hygiene, and (c) habits and customs associated with the preparation of foods. Brucellosis in humans can be prevented by attention to these issues, most notably the prevention of brucellosis in animals through immunization.[123]

9.2. Chemotherapy and Prophylaxis

A variety of antimicrobial agents are effective for treating brucellosis, but in vitro susceptibility does not always predict clinical effectiveness.[124] The most effective therapy for human brucellosis is doxycycline (100 mg twice daily by mouth for 6 weeks) plus either streptomycin (1 g intramuscular for 2–3 weeks) or gentamicin (5 mg/kg/day intramuscularly for 1 week).[125] An alternative and completely oral regimen is doxycycline (100 mg twice daily by mouth) plus rifampin (600–900 mg daily by mouth) both given for 45 days. Although this regimen gives comparable results for uncomplicated illness, the relapse rates are higher in patients with osteoarticular complications.[126] For the treatment of brucellosis in children less than 8 years of age and pregnant women, for whom tetracycline is contraindicated, trimethoprim–sulfamethoxazole (TMP/SMZ; four tablets each containing 80 mg TMP/400 mg SMZ) daily by mouth for a minimum of 21 days has been recommended. The optimal treatment of brucella endocarditis and neurobrucellosis has not been determined. Most authorities recommend combination of drugs, including doxycycline, rifampin, and TMP/SMZ administered for prolonged periods of time. Some quinolones have good in vitro activity, but are not first-line therapy even when combined with other drugs.[127]

9.3. Immunization

Vaccines for use in animals were used at one time to immunize humans at high risk in the Soviet Union and China. Such vaccines are not approved for human use in the United States as they are live vaccines and have the potential to cause infection. Inactivated brucella vaccines and various antigenic preparations have been studied in humans, but to date they have not proven effective.

10. Unresolved Problems

With the importance of *Brucella* spp. as potential biowarfare agents, there is a need for a vaccine to protect humans. Because live vaccine strains have the potential for producing illness, there is interest in subunit vaccines that are not pathogenic, but will induce long-lasting immunity. To this end, there is a need to determine virulence antigens against which subunit or DNA vaccines can be directed.

CHAPTER 9

Campylobacter Infections

Ban Mishu Allos

1. Introduction

Campylobacters are slender, spiral or curved, microaerophilic gram-negative rods that are one of the most commonly reported bacterial causes of diarrhea in the developing and developed world. Campylobacters also may cause systemic illness in humans and a number of diseases in wild and domestic animals. Because of morphological similarity with vibrios, these organisms were originally classified as *Vibrio fetus*.[1] *Campylobacter* (Greek for "curved rod") was proposed as a name of a new genus when it was found that these organisms differed in their biochemical characteristics from true members of the genus *Vibrio. C. jejuni* is now regarded as among the leading causes of diarrheal disease in humans. The complete genomic sequence of *C. jejuni* was characterized in 2000.[2] This may open the door for new insights into the behavior of these organisms. Worldwide, more than 80% of *Campylobacter* isolates implicated in human disease are *C. jejuni*; however, culture media commonly used to identify campylobacters may not support other potentially pathogenic *Campylobacter* species. Other *Campylobacter* or *Campylobacter*-like species that have been associated with human disease include *C. coli, C. fetus*, subsp.*fetus, C. lari, Helicobacter fennelliae, H. cinaedi, C. hyointestinalis, C. upsaliensis, C. jejuni* subsp. *doyleii, C. sputorum*, and*Arcobacter butzleri* (Table 1). *C. fetus* subsp. *fetus* also causes systemic infections in immunocompromised hosts. Some campylobacters and related species such as *C. nitrofrigilis*, *A. cryaerophila*, and *C. concisus* have not yet been associated with human disease. *Helicobacter pylori* is associated with gastritis, peptic ulcer disease, and gastric cancer in humans. *H. pylori* will not be discussed in this chapter.

Ban Mishu Allos • Division of Infectious Diseases, Vanderbilt University School of Medicine, Nashville, Tennessee 37232, USA.

2. Historical Background

The first identification of *Campylobacter* was in 1909, during an investigation of infectious abortion, when MacFadyean and Stockman,[3] two English veterinarians, isolated organisms from placentas and aborted fetuses of cattle that they called *Vibrio fetus*. Subsequently, similar organisms were found to cause infectious abortion in sheep.[3] *V. fetus* became known as a major cause of enzootic and epizootic abortion in cattle and sheep.[4] Over the next 30 years, these organisms were isolated from calves[5] and swine with diarrhea[6] and from fowl with hepatitis and diarrhea.[4] Although *V. fetus* was at first believed to cause diarrheal illness in these hosts, this association has not been clearly documented.

The first isolation of *V. fetus* from a human was in 1947 from the bloodstream of a pregnant woman who had an infectious abortion.[7] Over the next 30 years, there were occasional reports in the medical literature of isolation of these organisms from the bloodstream, cerebrospinal fluid, joint aspirates, endovascular tissue, and abscess cavities. Most of the hosts were debilitated by alcoholism, neoplasm, diabetes mellitus, cardiovascular disease, or old age.[8,9] *V. fetus* was thought to be an unusual cause of systemic illness in debilitated hosts, and it was thus considered to be an opportunistic organism. However, in 1957, Elizabeth King[10] at the Communicable Disease Center (CDC) recognized that not all the *V. fetus* organisms were the same; she identified two groups with distinct serological and biochemical characteristics. The majority of the isolates grew at 25 and 37°C, but the rest grew only at 37 and 42°C. She called this latter group "related vibrios" and noted that although they were isolated from the bloodstream; in each case the patient had had a diarrheal illness. She postulated that the related vibrios caused acute diarrheal illness, but because they were slow growing and fastidious, they could not be isolated from fecal specimens.[10]

[o] Spreading, noncolonial growth.
[p] Hypochlorite odor.
[q] Aerobic growth occurs at 30°C.

Based on King's and his own observations that the related vibrio was associated with diarrhea, Bokkenheuser[8] concluded that this organism was probably present in feces, but could not be detected with the available laboratory techniques. Cooper and Slee[11] in Australia isolated *V. fetus* (*C. jejuni*) from the stool of an immunocompromised patient with recurrent bacteremia and diarrhea by inoculating the patient's feces onto a horse blood agar plate containing cephalothin disks and incubating it overnight in a carbon dioxide-enriched atmosphere. In 1972, Dekeyser et al.[12] reported a positive stool culture for *Campylobacter* from a 22-year-old woman from whom *C. jejuni* had been isolated from the blood. The stool isolate was obtained by filtering fecal specimens through a 0.65 μm Millipore filter with a syringe. Using this filtration procedure, Butzler et al.[13] were able to isolate *Campylobacter* from 5.1% of 800 children in Brussels with diarrhea and only 1.3% of 1,000 children without diarrhea. Skirrow[14] showed that an agar medium containing antibiotics could be used instead of filtration as a primary isolation technique and that *C. jejuni* was as important a cause of diarrheal disease in England as Butzler et al.[13] had found it in Belgium. The use of antibiotic-containing selective media combined with simple methods for obtaining a microaerobic atmosphere have made isolation of *Campylobacter* a routine procedure and have opened up the study of *Campylobacter* infections on a worldwide scale. In 1973, Veron and Chatlain[15] reported that *V. fetus* and related vibrios had biochemical characteristics dissimilar

to those of the Vibrionaceae, and a new genus, *Campylobacter*, was proposed. Under this scheme and later modification by Smibert,[4] King's related vibrios became *C. jejuni* and *C. coli*, and the opportunistic organisms became *C. fetus* subsp. *fetus*, respectively.[1,15]

New members of the genus *Campylobacter* and related genera are being identified with regularity. Some Campylobacters, particularly the hippurate-negative group, are not thermotolerant and are susceptible to antibiotics, such as cephalothin and colistin, that are incorporated into selective isolation media. These *Campylobacter* can be isolated at 37°C on media without antibiotics by inoculating a stool suspension directly on a 0.45 μm Millipore filter that has been placed directly on a blood agar plate.[16] Using these and other similar methods, increasing numbers of these organisms have been isolated from humans with gastrointestinal illness, suggesting that "atypical" campylobacters play a greater role in causing human disease than previously thought.[17] Nevertheless, at present, *C. jejuni* remains the most important cause of diarrheal disease in this group, and the importance of these "related" campylobacters as human pathogens has not yet been fully defined.

3. Methodology

3.1. Sources of Mortality Data

Limited information is available concerning the importance of *Campylobacter* in fatal diarrheal disease; however, judging from the frequency of *Campylobacter* infection in patients ill enough to seek medical attention, the bacterium may be a major cause of mortality due to diarrheal disease. In developed countries in recent years, mortality due to diarrheal diseases has been low. Several deaths due to infection by *C. jejuni* have been reported, which have allowed for limited population-based estimates of mortality.[18] The uncommon human infections with *C. fetus* subsp. *fetus*, usually occurring in debilitated hosts, have sometimes been fatal.[8] Campylobacter infections occurring in persons with human immunodeficiency virus (HIV) infection or other immunodeficiencies may be associated with higher mortality rates. Guillain–Barré syndrome and the hemolytic–uremic syndrome are uncommon complications of *C. jejuni* infections that are also potentially fatal (Section 8.1).

3.2. Sources of Morbidity Data

Because campylobacters produce diarrheal illnesses that are usually indistinguishable from those caused by other viral and bacterial enteric pathogens, it is not possible to obtain data on morbidity in the absence of laboratory identification of the organism. Most data on morbidity in Europe and the United States come from hospital-based or community-based studies of *Campylobacter* infections.[19–21] Estimates of incidence in HIV-infected persons are made by studying patients in AIDS clinics.[22,23] Surveys from hospitals and clinics have also been conducted in developing countries. At the International Center for Diarrheal Disease Research in Bangladesh, surveillance is based on culturing 4% of patients who come to the center with acute diarrheal disease.[24] In England and Wales, 200 public health and hospital laboratories report *Campylobacter* isolations to the Communicable Disease Surveillance Center.[25] In the United States, *Campylobacter* isolations are routinely reported to the Centers for Disease Control and Prevention (CDC).[26] Outbreaks of *Campylobacter* infection are routinely reported to the CDC *Campylobacter* National Surveillance system.[26]

3.3. Serological Surveys

Serological surveys using one or several antigens common to the majority of *Campylobacter* strains have been performed among healthy populations in the United States, Bangladesh, and Thailand.[27–29] Surveys have been made to confirm the diagnosis in patients with diarrhea, to investigate outbreaks, to determine the etiology when multiple pathogens were isolated, to investigate occupational exposure and other high-risk groups,[30,31] and to investigate the association of *Campylobacter* with postinfection complications such as reactive arthritis and Guillain–Barré syndrome.[31,32] The Foodborne Diseases Active Surveillance Network (FoodNet) of the CDC's Emerging Infections Program collects data from 10 US states regarding diseases caused by enteric pathogens including Campylobacter.[32]

3.4. Laboratory Diagnosis

Stools or rectal swabs, the usual specimens submitted to the laboratory for examination, are inoculated onto selective media to permit isolation of *Campylobacter*. A transport medium such as Cary–Blair should be used if a delay of more than 2 h is anticipated before arrival of the specimen to the laboratory.[33] The three most commonly used selective media for isolation of *C. jejuni* or *C. coli* are Skirrow's,[14] Butzler's,[34] and Campy–BAP,[35] all with rich basal media enriched with sheep or horse blood and all containing antibiotics to inhibit the normal enteric flora. Skirrow's medium is the least inhibitory to the enteric flora; however, in most patients with *Campylobacter* enteritis, the titer of

Campylobacter organisms per gram of stool ranges from 10^6 to 10^9,[36] a quantity easily detected with this medium. Butzler's media, Virion, which contains cefaperazone and is more inhibitory to competing flora, also appears to be very useful.[37] Blood-free media containing antibiotics have also been used successfully,[38] and several enrichment media have been found to support the growth of *Campylobacter.*[37] Enrichment methods are probably not necessary for detection of *Campylobacter* is diarrheal stools, but may be useful in detecting carriers. A combination of blood-free media such as cefoperazone deoxycholate agar and charcoalbased selective medium may achieve the highest yield of *C. jejuni* or *C. coli* from stool specimens.[39]

Many campylobacters that cause diarrhea are inhibited by cephalothin or colistin, which are present in selective media, or by incubation at 42°C.[16,40] In the United States, more than 99% of reported *Campylobacter* isolates are *C. jejuni.*[26] This predominance probably reflects the types of culture media routinely used for the detection of campylobacters in this country. In studies where antibiotic-free media or filtration methods are used, the proportion of campylobacters that are non-*jejuni* species is over 20%. Both Campy–BAP and Butzler's media contain cephalosporins, which inhibit most strains of *C. fetus* subsp *fetus* and many of the "atypical" organisms; for this reason, the potential of these organisms to cause human disease may be underappreciated.[41,42] Steele demonstrated a 0.45 μm cellulose acetate membrane filter placed directly on an antibiotic-free blood agar plate could be used to isolate *Campylobacter* at 37°C.[16] *Campylobacter* in saline solution is able to pass through the filter while other fecal flora do not. A 0.65 μm filter may offer better isolation rates than the 0.45 μm, although the number of contaminating bacteria is also increased. Because the yield for detecting atypical campylobacters is so much higher with a filter and nonselective medium such as chocolate agar,[17] this technique is now recommended for primary isolation of campylobacters from feces or rectal swabs.

Campylobacters require an atmosphere with an oxygen concentration of 5–10% for optimal growth. A microaerobic atmosphere may be produced by using *Campylobacter*-specific gas-generating kits[43] or by evacuating vacuum jars or bags and refilling with a mixture of 5% oxygen, 10% carbon dioxide, and 85% nitrogen. Campylobacters are capnophilic, although carbon dioxide is not essential for growth incubation of plates in a candle jar may permit isolation from most positive specimens, but should best be used at 42°C.

When using selective antibiotic media, optimal isolation of *C. jejuni* is obtained at an incubation temperature of 42°C; however, some *Campylobacter* species cannot be isolated at that temperature (Table 1). All organisms will grow at 37°C. When using the more selective media, the higher temperature for incubation is recommended. If the membrane filter method is employed, the optimum incubation temperature is 37°C.

After incubation of cultures under these conditions for 24–48 hr, colonies that are gray, mucoid, or wetappearing, or discrete should be suspected of being *Campylobacter* and may be identified as such using standard biochemical tests (Table 1). A rapid presumptive identification can be made by the following characteristics: (1) typical colonial morphology, (2) typical Gram's stain showing gram-negative curved rods, (3) indication of oxidase and catalase positivity, and (4) motility. *Campylobacter* can be isolated from body fluids or tissues that do not have a normal flora by using thioglycollate broth or biphasic media. Some commercial blood culture systems are superior to others for detection of bacteremia due to *Campylobacter* species.

Direct examination of stools has been used as a rapid screening test for *Campylobacter* in developed countries.[44–46] These methods are usually specific, but are only about 50–75% sensitive. Staining with 1% aqueous basic fuchsin was reported to be the most sensitive method.[45] Sensitivity was increased in the presence of fecal leukocytes.[46] Serological diagnosis is possible in which antibodies to the homologous strain or to a common acid-extracted antigen are detected.[27]

A biotyping scheme for *C. jejuni, C. coli*, and *C. laridis* strains has been developed that is based on hippurate hydrolysis, rapid H_2S production, and DNA hydrolysis.[47] A phage-typing system has also been developed for *C. jejuni* and *C. coli.*[48] The two most widely used serotyping systems for *C. jejuni* and *C. coli* are the Penner system, which identifies soluble, heat-stable (somatic, O) antigens by passive hemagglutination,[49] and the Lior system, which measures heat-labile (flagellar, H) antigens by slide agglutination.[50] There are over 90 reference serotypes defined by the Penner system and 112 by the Lior system. Both systems identify over 90% of *Campylobacter* isolated from humans and nonhuman sources.[51,52] The Lior system is easier to use and more rapid and consequently more applicable for use outside reference laboratories.[53] Strains of a single serotype in one system may belong to multiple serotypes in another system. These two systems may eventually be combined to produce a system similar to *Escherichia coli* serotyping based on both O and H antigen grouping. Polymerase chain reaction (PCR)-based techniques for identification and typing of Campylobacter species also are now available.[54–56]

4. Proof of Causation and Biological Characteristics of the Organism that Affect the Epidemiological Pattern

The evidence that *C. jejuni* is an etiologic agent for human diarrheal disease can be summarized as follows: (1) In developed countries, *Campylobacter* has been isolated from the stools of 3–14% of patients presenting at hospitals with diarrhea, but only rarely from stool samples of controls (Table 2). (2) Outbreaks of gastrointestinal illness have occurred among previously healthy populations in which no other pathogen has been found, and *Campylobacter* has been isolated from the stools of patients but not from controls (Section 6). (3) In natural settings and in experimental models, *Campylobacter* has caused diarrheal illness in avian species[57] and in mammals such as puppies[58] and nonhuman primates.[59] (4) In several patients who had diarrheal illness, *Campylobacter* was simultaneously isolated from stool and blood.[10–12] (5) Rising titers of specific serum antibody to the infecting organisms have been shown.[27,35] (6) Treatment of ill *Campylobacter*-infected patients with erythromycin, an agent to which most other recognized enteric pathogens do not respond, has been followed by rapid clearance of organisms and rapid remission of symptoms.[60] (7) Two volunteers ingested organisms in a glass of milk and developed a typical gastrointestinal illness after 3 days, and *Campylobacter* was isolated from their stools.[61] (8) Finally, two strains of *C. jejuni* isolated from persons with diarrhea were fed to 111 American adult volunteers with sodium bicarbonate.[62] The minimum infective dose was 1,000 organisms. With one strain (81–176), all became infected (i.e., *Campylobacter* was isolated from their stools) and 18 (46%) of 39 developed diarrhea with fecal leukocytes or fever after ingestion of 10^6 organisms. The findings thus fulfill the Henle–Koch postulates of causation (see Chapter 1, Section 13).

Campylobacters grow best at the body temperatures of warm-blooded hosts. *C. jejuni* has been identified as a part of the enteric flora in swine, dogs, cats, nonhuman primates, rodents, cattle, sheep, and other ruminants.[4]

Optimal growth occurs at 42°C, the body temperature of fowl, and *C. jejuni* appears to be commensal in adult domestic fowl. *Campylobacter* appears to be an enteric pathogen for primates,[59] but its role as an enteric pathogen in other animal species is not well defined.

Viability of organisms under environmental conditions is temperature dependent. *C. jejuni* will survive for weeks in water, feces, urine, and milk when kept at 4°C; however, at 25°C, viability persists for a few days or less.[36] *Campylobacter*, like *Salmonella*, is quite sensitive to low pH and will not survive longer than 5 min at a pH less than 2.3. At neutrality or alkaline pH, especially in bile, organisms may multiply and survive up to 3 months at 37°C.[36]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

C. jejuni is an important cause of diarrheal illness in the developed and developing world and in all age groups. Prevalence of *disease* caused by *Campylobacter* is based on the rate of isolation of the organism from patients with diarrheal illness. Inferences drawn from such studies must be tempered by knowledge of the data artifacts implicit in laboratory-based culture surveys. Defining the presence of *infection* due to *Campylobacter* in a community includes prevalence of isolation of the bacterium from the stools of healthy persons and the presence of antibodies to *Campylobacter* among a representative population sample.

Campylobacter infections have been evaluated as part of surveys on the etiology of diarrheal disease among persons coming to the hospital or clinic. In the developed world, *Campylobacter* ranks among the most commonly isolated bacterial pathogens from persons with diarrheal disease and is uncommonly isolated from populations of healthy controls (Table 2). Studies in communities, cities, and states in the United States, England, and Israel show that the rate of reported *Campylobacter* isolations ranges from 1.4 to 100 per 100,000 population per year.[18,25,63,64] Rates of *Campylobacter* infections vary according to the age distribution and location of the study population. The rate of *Campylobacter* isolation in the United States reported to the CDC has been stable at 5–6 per 100,000 population since 1982.[26] Because not all hospital laboratories routinely culture diarrheal stools, this reported rate likely represents an underestimate of the true rate of *Campylobacter* infections.

Two prospective studies document the true incidence of campylobacters relative to salmonellae and shigellae. In the first, eight hospital microbiology laboratories routinely looked for campylobacters every time they cultured stools for other pathogens. *Campylobacter* was isolated twice as frequently as *Salmonella* and 4.5 times as frequently as *Shigella.*[19] In the second study, a Seattle health maintenance organization (HMO) cultured all diarrheal stools for the same three pathogens. Campylobacters were again isolated twice as frequently as salmonellae and seven times as frequently as shigellae.[65] Because the reported rate of *Salmonella* infections is 20 per 100,000 population, if clinical laboratories cultured diarrheal stools as often as they cultured them for salmonellae, the incidence of *Campylobacter* infections would be twice this rate—40 per 100,000 population. Similarly, in a 1999 CDC study, date were collected on foodborne infections from numerous sources including several surveillance systems, surveys, and other published population-based studies.[66] They estimated a total of 2.4 million cases of *Campylobacter* infection occurred in the United States each year—more than the estimated number of cases of *Salmonella* (1.4 million) and *Shigella* (448,240) combined.

Campylobacter infections may be more underreported than other bacterial enteric infections because of the mildness of many infections; patients might not find it necessary to seek medical care. In a community-wide outbreak of *C. jejuni* infections caused by a contaminated water supply, only 1 of 18 symptomatic persons sought medical care.[67] In another outbreak at a summer camp, only 4 (10%) of 41 infected persons were sufficiently ill to seek medical attention.[68] These and other studies indicate that the true annual incidence of *Campylobacter* infections in the United States is 1,000 per 100,000 population.[26] Similarly, in England the reported rate of *Campylobacter* infections is only 20 per 100,000 population per year; however, studies at the level of community-based physicians also showed that the true annual incidence is 1,100 per 100,000 population.[20] The case-fatality rate for *Campylobacter* infections has been estimated at 0.05 per 1,000 cases.[18]

Most recently, surveillance for *Campylobacter* infections has shown a downward trend in rates of infection. According to the active population-based surveillance network, FoodNet established by CDC and other federal agencies, the incidence of *C. jejuni* infections per 100,000 population in the United States fell by more than 30% from 21.7 in 1998 to 12.9 in 2003.[32]

The epidemiology of *Campylobacter* infections is markedly different in tropical developing countries. In such countries, *Campylobacter* infection is hyperendemic and asymptomatic infection may be frequent (Table 3). In countries such as Bangladesh, South Africa, The Gambia, Zaire, India, Australia, Indonesia, and China, the rate of *Campylobacter* infections is greatest in infants and declines with age.[69] Estimates from laboratory-based surveillance suggest the incidence of this infection among children less

[a]Presented at the IV International Conference on *Campylobacter* infections (1987).

than 5 years old may be more than 100 times higher than the rate in developed nations.[70] The case-to-infection ratio is probably quite high and varies inversely according to age, suggesting that immunity is an important factor.[71,72] Furthermore, adults naturally and experimentally infected with *C. jejuni* were less susceptible to illness if they had preexisting antibody titers to *Campylobacter.*[73,74] *Campylobacter* infections are an important cause of childhood morbidity from watery diarrhea in developing countries.

5.2. Epidemic Behavior

In addition to endemic infection, outbreaks of disease associated with *Campylobacter* regularly occur in developed countries. Outbreaks do not occur where *Campylobacter* infections are hyperendemic, such as in many areas of the developing world, probably because of a high prevalence of postexposure immunity.[28] Outbreak investigations have provided much of the information about specific vehicles for transmission of infection (Section 6).

Investigations of outbreaks have shown that asymptomatic infection may occur in those exposed to an implicated vehicle[68,75,76] and that the spectrum of illness produced may be broad. Secondary spread of infection does occur in close contacts such as family members. In follow-up studies in Israel, 20 (10%) of 200 family contacts were found to excrete *Campylobacter*.[77] However, in most sporadic cases the source is not known and it is difficult to distinguish co-primary from secondary infections.

5.3. Geographic Distribution

Campylobacter infections are present in all parts of the world, as documented by studies of diarrheal disease on all inhabited continents (Tables 2 and 3). Isolations have been made from patients in tropical, temperate, and Arctic climates. Travelers who have acquired *Campylobacter* infections in every region of the world represent a considerable proportion of the total cases in Scandinavian countries.[78,79] Similarly, persons from developed countries who are living in developing countries are also at risk for *Campylobacter* infection.[80] In northern climates such as Canada[81] and Iceland,[82] *Campylobacter* infections are reported more commonly among persons in rural areas. In Ontario, Canada, the annual case rate was 80 per 100,000 in urban or nonfarm areas and 350–400 per 100,000 in farm areas where cases were often associated with raw milk ingestion.[81] High isolation rates in rural areas of Africa have been attributed to close association with domestic animals.[83]

The prevalence of *Campylobacter* infection is higher in developing than in developed areas (Table 3). *Campylobcter* infections appear to be increasing in developing countries and in some areas are surpassing *Shigella* and *E. coli* as causes of diarrhea.[84] Studies of healthy children in rural South Africa,[85] rural Bangladesh,[86,72] Central African Republic,[71] and The Gambia[87] found that asymptomatic infection of young children was prevalent. In The Gambia, 7.6% of asymptomatic children 2–4 years old were infected, and in both South Africa and Bangladesh, 40% of healthy children 9–24 months old were culture positive on a single determination. In a longitudinal study, *Campylobacter* infections were found in 41% of 127 children who were cultured biweekly from birth until 6 months of age.[71] As a consequence of continued and widespread exposure to campylobacters, in developing countries there is no difference in the isolation rate of *Campylobacter* from children with and without diarrhea. Furthermore, because infection and immunity are acquired early in life, *Campylobacter* infections are uncommon in adults in developing countries; no difference in isolation rates was observed among adults with and without diarrhea in Bangladesh.[88] After infection, the duration of excretion of *Campylobacter* is shorter (about 7 days) than it is among persons in developed countries. The high *Campylobacter* isolation rate among persons with diarrhea is caused by frequent transmission of organisms among the population rather than prolonged convalescent excretion.[89]

5.4. Temporal Distribution

In industrialized countries in temperate climates there is a definite increase in isolation rate during the hot summer months and a definite decrease during the cold winter months.[90,91] In Scandinavian countries there is another peak after winter holiday seasons resulting from infections in travelers.[78] In tropical, developing countries there is usually no seasonal variation.[72]

5.5. Age and Sex

In industrialized countries there is a bimodal age distribution. The largest peak occurs in children less than 5 years old and a second peak occurs in young adults 20–29 years old (Figure 1A). Among hospitalized patients, a third peak is observed among persons 60–80 years old.[29,79] In *Campylobacter* infections among children and young adults, males usually predominate[26] (Figure 1A), and among older persons the ratio is equal or in favor of females. In Colorado, for example, males predominate in all age groups under 40 and the greatest difference between sexes was in infants, where the male-to-female ratio was over 2:1.[90] The reason for the higher rate in males remains unexplained. In keeping with the second peak of isolation in young adults, *Campylobacter* is the predominant cause of diarrheal disease at American universities.[91] Eating under-cooked chicken and close association with cats are recognized risk factors among university students.[91,92]

In developing countries, isolation rates are highest among children less than 1 year old and do not increase again in young adults (Figure 1B). The highest isolation rate occurs in children 6–12 months old (Figure 1B inset). In developing countries, one to two *Campylobacter* infections per year for children under 5 years of age would be a conservative estimate. Serological surveys among healthy persons have shown a speak in *Campylobacter* IgG antibodies in children aged 1 year in Thailand and ages 2–4 years in Bangladesh.[28] Infection, even in infants, is frequently not associated with disease in areas of hyperendemicity.[71]

5.6. Occupation

There have been reports of infection immediately after occupational contact with cattle and sheep or with

beef, swine, or chicken carcasses.[93,94] At present, there is no information to suggest that hospital personnel are at increased risk of infection.

5.7. Other Factors

Campylobacter infections may also be sexually transmitted in homosexual men.[95] Two species, *Helicobacter cinaedi* and *H. fennelliae* have been isolated from homosexual men,[40,96] as have *C. fetus* subsp. *fetus*[97,98] and *C. hyointestinalis*. Homosexual men who have been infected with multiple etiologic agents appear to be at an increased risk of these *Campylobacter* species of low virulence. Prolonged or unusually severe *C. jejuni* infections have been recognized in patients with hypogammaglobulinemia or acquired immunodeficiency syndrome (AIDS) (Section 8.1). Most patients infected with *C. fetus* subsp. *fetus* have been debilitated or compromised by chronic disease or were at the extremes of age.[41,97,99] Since most *C. fetus* subsp. *fetus* infections are detected by blood culture, it is possible that only the severe end of the spectrum of disease is recognized. When *C. fetus* subsp. *fetus* was isolated from stool in a milk-borne outbreak, it caused a diarrheal disease indistinguishable from *C. jejuni*.[42]

5.8. Atypical *Campylobacter* Species

In places where antibiotic-free media or filtration methods are used, the proportion of non-*jejuni* campylobacters is >20% and in some countries approaches 50%[100–102] especially in tropical developing countries.. These organisms are increasingly recognized as human pathogens, perhaps in all populations but especially in immunocompromised persons (Table 1).[103–105]

C. fetus typically causes bacteremia or other extraintestinal infections in immunocompromised hosts.[106–109] This species also may cause uncomplicated diarrhea in immunocompetent persons.[100] *C. fetus* infections may be transmitted to humans via raw milk or other raw or undercooked foods of bovine or ovine origin.[42] *C. upsaliensis* is a catalase-negative, thermotolerant *Campylobacter* that causes diarrhea in young children; the organism has also been isolated from blood.[42,111] *C. upsaliensis* was first isolated from dogs, which are the principal reservoirs for this organism. In some parts of the world, such as South Africa and the Netherlands, more than 10% of all *Campylobacter* isolated are *C. upsaliensis*.[105,112] *C. upsaliensis* strains from different continents exhibit substantial differences in their genomic characteristics.[113] *C. hyointestinalis*, a causal agent of proliferative enteritis in swine, also has been associated with watery, nonbloody diarrhea in young children and in adults.[114,115] *C. lari* (formerly *C. laridis*) is found in 25% of healthy seagulls; this *Campylobacter* can produce acute diarrheal illness in young children and has been isolated from the blood of immunocompromised persons.[116,117]

Helicobacter cinaedi and *H. fennelliae* are a cause of enteritis and proctocolitis in homosexual men and sometimes also may cause bacteremia.[117–125] Malnourished children in developing countries also are susceptible to infection with these organisms.[120] Recent studies suggest these organisms may cause diarrheal disease in immunocompetent and heterosexual populations as well.[121] *Arcobacter cryaerophila* and *A. butzleri* were moved from the *Campylobacter* genus in 1991; both organisms can cause gastroenteritis.[122,123] *C. jejuni* subsp *doylei* has been isolated from the stools of children with diarrhea.[124] The organism also has been isolated from blood, usually in children with gastrointestinal symptoms, suggesting an intestinal source of infection. H2-requiring Campylobacters (*C. concisus, C. rectus, C. curvus, C. mucosalis*) have been associated with periodontal disease.[125] Their role as gastrointestinal pathogens has not been established.

6. Mechanisms and Routes of Transmission

Transmission of *Campylobacter* appears similar to that for other known enteric pathogens, i.e., transmission by way of contaminated food and water or by oral contact with fecal material from infected animals or humans. This information comes from investigation of several large and small outbreaks and from case–control studies of sporadic infections.

In developed countries, most *C. jejuni* infections are acquired through consumption and preparation of chicken. Microbiologic surveys have shown that chicken carcasses are nearly always contaminated with *Campylobacter.*[126] It is, therefore, perhaps not too surprising that in case–control studies of sporadic *C. jejuni* infections, up to 70% of cases are associated with eating chicken.[127–130] The greatest risk of infection comes from eating chicken prepared outside the home. Serological surveys indicate increased exposure to *Campylobacter* among poultry workers.[94] Other outbreak reports have implicated cross-contamination of foods in kitchens as a source of human infection and illness.[131,132]

Other foods of animal origin (e.g., beef, pork) may occasionally be related to *C. jejuni* infection.[133]Eating sausages was shown to be an important risk factor for sporadic cases of *Campylobacter* infection in Norway.[134] Nonmeat products such as mushrooms may be contaminated in the soil.[135]

In contrast to sporadic cases, outbreaks of *C. jejuni* infection are associated most commonly not with eating

chicken but with drinking raw milk.[136] From 1972 to 1990, 20 raw milk-associated outbreaks involving 458 people occurred among children and teenagers.[137] Fecal excretion of *Campylobacter* in milk cows and cattle is common and probably the usual source of contamination. *Campylobacter* infection of the bovine udder (mastitis) also may be a source of milk contamination. *Campylobacter* remains viable in refrigerated milk for 3 weeks and when ingested in milk may be protected from the effect of gastric acid.[36] As few as 500 *Campylobacter* cells are infective when given with milk.[61] Persons who regularly drink raw milk have elevated levels of antibodies to *Campylobacter* compared to age-matched persons who do not drink raw milk.[73] *C. fetus* subsp. *fetus* also has been associated with diarrheal disease after the ingestion of raw milk.[42] In the United Kingdom, pasteurized, bottled milk may be a source of *Campylobacter* infections because of contamination of the milk by birds (magpies and jackdaws) pecking the milk bottle tops.[37]

Waterborne outbreaks of *Campylobacter* infections have been reported in the United States, Europe, and Israel.[67,75,139–142] In the two largest outbreaks affecting 3,000 persons in Vermont[141] and 2,000 persons in central Sweden,[139] untreated surface water most likely contaminated drinking water systems. In smaller outbreaks at an English boarding school[140] and in a Florida town,[67] water in open-topped storage tanks became contaminated perhaps by feces from birds or rodents. During heavy rains, an untreated water reservoir in a Norwegian community was contaminated with sheep feces; 680 (66%) of the 1,021 community residents who drank the water developed symptomatic *Campylobacter* infection.[75] In a national park in the Rocky Mountains of the western United States, ingestion of untreated surface water was the most important risk factor for *Campylobacter* infection, which was found to be a more common cause of diarrhea than giardiasis.[141] In Colorado, ingestion of raw water is an important risk factor for sporadic cases.[143] *C. lari* was the probable cause of a waterborne outbreak among 162 construction workers in Canada when lake water was cross-connected to the main drinking water supply.[28] This outbreak provided convincing evidence that *C. lari* was a human diarrheal disease pathogen.

C. jejuni infections have been associated with foreign travel[144,145] and with exposure to dogs and cats.[146,147] Since the animal species with which humans come into contact most frequently—including dogs, cats, cattle, sheep, goats, chickens, turkeys, swine, horses, and rodents[148]—have been shown to excrete *C. jejuni* in their feces, the potential reservoir for human infection is enormous. Serotypes of *Campylobacter* isolated from animals are essentially the same as those isolated from humans.

As with other enteric infections, infected humans may be a reservoir for further transmission of infection, but *Campylobacter* is microaerophilic and sensitive to desiccation. Person-to-person transmission has been reported;[149] however, the index case has usually been a young child not yet toilet trained. There have been several reports of vertical transmission of *Campylobacter* infection from symptomatic or asymptomatic mothers to their neonates.[150,151] A contaminated bath plug may have caused an outbreak of *C. jejuni* infection among 11 children in the neonatal and pediatric intensive care units of a Dutch hospital.[152] Among 19 reported cases of premature labor, abortion, and perinatal sepsis due to *Campylobacter* species, *C. fetus* subsp. *fetus* was isolated in 9 and *C. jejuni/coli* in 10.[153] Considering that *C. jejuni* infection is many more times (ca. 500) more common than *C. fetus* subsp *fetus* infection, *C. fetus* must be considered to have a propensity for these complications.[41] Neonatal infections may be severe. A nosocomial outbreak of meningitis occurred in a neonatal nursery in France.[154] Transmission via infected food handlers or health care workers has been described but is rare.[155] There has been a report of laboratory-acquired infection,[156] but transmission to hospital personnel from patients or specimens in the hospital appears to be uncommon. Unlike *Shigella*, *Giardia*, or hepatitis A infections, there have been no outbreaks of *C. jejuni* infection reported in daycare centers or institutions for the mentally retarded.

7. Pathogenesis and Immunity

The minimal dose of *Campylobacter* that produces human infections is not known. A volunteer who ingested 10^6 organisms in milk became ill within 3 days;[153] however, infection has been induced with as few as 500 organisms.[61] In general, attack rates have been dose dependent in volunteer studies.[62,157] In a large milk-borne outbreak, almost all patients experienced the onset of illness within 2–7 days of drinking the contaminated milk.[158] For most pathogens, the length of the incubation period is inversely related to the dose ingested. The marked sensitivity of *Campylobacter* to gastric pH[36] suggests that it would take a high dose to infect 50–100% of subjects. The ID_{50} when given with sodium bicarbonate was 10^8.[62]

All campylobacters have a flagellum at one or both ends; the organisms' motility contributes to their ability to colonize and infect the intestinal mucosa.[159–161] Infection leads to multiplication of organisms in the intestine; patients shed 10^6–10^9 *Campylobacter*/g stool,[36] concentrations similar to those in *Salmonella* and *Shigella* infections. The sites of tissue injury include the jejunum, ileum, and

colon,[36] although whether the small or large intestine is more commonly affected is not known. In both organs, acute exudative and hemorrhagic inflammation may occur, and the appendix, mesenteric lymph nodes, and gallbladder may also be affected by the inflammatory process.[14] Patients with severe clinical manifestations frequently have colonic involvement. The pathological lesion may include infiltration of the lamina propria with acute and chronic inflammatory cells and destruction of epithelial glands with crypt abscess formation. This nonspecific colitis may mimic that seen in other types of infectious colitis, acute ulcerative colitis, or Crohn's disease. A pseudomembranous colitis has also been described.

A choleralike enterotoxin has been described by some researchers,[99,151,162,163] but others have been unable to reproduce these results.[74] More than 20 years after this toxin was first described, considerable evidence suggests that it does not exist. Enterotoxic activity is not found in fecal specimens from *C. jejuni*-infected persons.[165] Furthermore, unlike persons with cholera or those infected with enterotoxigenic *E. coli* persons infected with *C. jejuni* do not possess antibodies to the putative toxin. Even if the presence of an enterotoxin were proven, its biological relevance would be questionable since the biological lesion of *C. jejuni* enteritis is inflammatory enteritis. A Shiga-like cytotoxin is produced in vitro by a small number of strains but only at very low titers.[166] The biological significance of this toxin is also uncertain. Increasing evidence suggests that *C. jejuni* is locally invasive,[167–169] although not in high numbers, and that infection with this organism possibly involves novel mechanisms. A protein that distends epithelial cella and is cytolethal is expressed by many *C. jejuni* strains but its role in pathogenesis has not been fully defined.[170,171]

Although strains have different pathogenic properties,[151] as yet there is no well-defined association between the clinical illness and any virulence property. The presence of bacteremia in some patients and the finding of cellular infiltration in biopsy specimens from patients with *Campylobacter* colitis suggest that tissue invasion may be one pathogenetic mechanism. Experimental challenges both in monkeys[172] and in vitro[173–176] confirm the invasiveness of *C. jejuni.* The process of *C. jejuni* invasion is multifactorial. After invasion, cellular architecture is altered. Microtubule-dependent mechanisms may be important in the organism's ability to invade the intestinal epithelium.[177] The bacteria's flagellae also are important virulence factors because they promote the motility and chemotaxis needed for *C. jejuni* to colonize the intestinal tract.[173,178] In vivo passage favors flagellated cells;[179] intact flagellar synthesis genes are required for maximal *C. jejuni* invasiveness.[180,181] A cytolethal distending toxin may affect cell cycle kinetics.[45,79] A high-molecular-weight plasmid also enhances the invasive capabilities of *C.jejuni* virulence.[183,184] *C. jejuni* may adhere to epithelial cells,[185] which favors gut colonization. A superficial antigen (PEB1) that appears to be the major adhesion[186] is conserved among *C. jejuni* strains, is a target of the immune response,[187] and may represent a vaccine candidate.[188,189] Chemotaxis[191] and production of fimbriae[191] also are important in virulence.

In developed countries over 50% of patients with enteritis caused by *C. jejuni* have bloody diarrhea,[19] while in developing countries the proportion varies from 10 to 30%.[72,89] *Campylobacter* serotypes show little geographic variation and there is no other strain difference that can account for the difference in the severity of the illness. Immunity to *Campylobacter* infection, which is higher among persons in developing countries, may prevent illness or modify the illness to a less severe form. Hippurate-negative *Campylobacter* strains may be less virulent than *C. jejuni*, which is hippurate positive. In most surveys from developed countries, hippurate-negative strains account for a small proportion of the total number of *Campylobacter* isolates; however, *C. coli* accounts for 30–40% of strains isolated in Hong Kong[192] and the Central African Republic,[193] a sufficient number to make an impact on the observed spectrum of illness.

Most intestinal isolates of *C. jejuni* are killed by normal human serum (serum-sensitive), while extraintestinal isolates may be either serum sensitive or serum resistant.[194] Extraintestinal isolates from normal hosts are usually serum resistant; those from impaired hosts are serum sensitive as are the intestinal isolates.[41]Serum resistance in *C. jejuni* strains has been associated with the total amount of lipopolysaccharide (LPS) produced.[41,195] The LPS may serve as a type of capsule that protects the organism from the killing activity of serum.

Studies in Canada,[196] the United States,[197] the United Kingdom,[158] and Sweden[21] have shown the median duration of excretion to be 2–3 weeks from onset of symptoms. Almost all patients were culture negative by 2 months. In developing countries the duration of excretion is 7–10 days.[72,89] A longer excretion period was observed in Thailand among children less than 1 year old (14 days) compared to older children (8 days), suggesting that previous immunity may shorten the convalescent excretion period.[89]

Patients infected with *Campylobacter* develop specific serum antibodies against a variety of *Campylobacter* proteins and its LPS.[27,198,199] The response to LPS is both species and type specific.[200] The IgM antibodies rise and fall earlier than the IgG and do not reach the height of the IgG titer rise. Titers of both classes of antibodies appear to decline within

several months of infection.[27] Serum antibodies developed in response to infection with one *Campylobacter* strain are cross-reactive with heterologous strains.[201] In developing countries, infection rates, case-to-infection ratios, as well as the duration and magnitude of convalescent carriage decline with age.[29,202] IgG antibody titers to *Campylobacter* antigens peak in the first few years of life and then decline, while IgA antibody titers continue to increase throughout life;[28] repeated infections may stimulate specific IgA production, but have little effect on systemic IgG production. After acute infection, IgA appears in the serum more rapidly than IgG and is predominantly in polymeric form.[203] Intestinal antibodies have also been detected.[204] Uninfected individuals have low-titer antibody to specific organisms. Volunteers with elevated serum and intestinal antibody levels to *Campylobacter* proteins become infected but are protected from illness. Similarly, habitual raw milk drinkers were protected from illness when exposed to contaminated raw milk that led to illness in other persons.[73] Little is known about the role of the cellular immune response in the control of *C. jejuni* infections. However, the increased severity and duration of these infections among HIV-infected persons suggest that cell-mediated immunity does play some role.

8. Patterns of Host Response

8.1. Clinical Features

The consequences of infection with *C. jejuni* vary from asymptomatic excretion to death. *Campylobacter* is rarely isolated in the stools of random selected, asymptomatic persons. However, in the setting of an outbreak, the infection-to-illness ratio may be high. In one large outbreak, 25% of those infected were found to be asymptomatic.[158] In another large outbreak >50% of infected persons were asymptomatic.[205]

The most common presentation of *C. jejuni* infection is an acute enteritis. In general, the symptoms and signs of *Campylobacter* infection are not so distinctive that the physician would be able to distinguish it from illness caused by other enteric pathogens. At the mild end of the spectrum, symptoms may last for 24 hr and be indistinguishable from those seen with a viral gastroenteritis. Such patients usually do not seek medical attention; the occurrence of those cases has been detected only in outbreaks.[68] In industrialized nations, bloody diarrhea or the presence of fecal leukocytes is often a helpful clinical indication of *Campylobacter* infection.

Most information on the clinical features of *Campylobacter* infection is based on hospital- or laboratory-based studies and is thus biased toward those who are the most severely ill and who have diarrheal illnesses. In a multicenter study[19] in the United States where diarrhea was the criterion for stool culture, *Campylobacter* infection was associated with abdominal pain (79%), fever $\geq$ 37.8°C (74%), and a history of bloody diarrhea (46%). Among those 10–29 years old, 31% of persons with a history of fever and ten or more fecal leukocytes had *Campylobacter* enteritis. The abdominal pain has been so severe on occasion as to mimic acute appendicitis.[14,206] Fever has been noted in up to 80% of these patients, although children have been febrile less frequently; convulsions have been reported. A prodrome of constitutional complaints, chiefly fever, may be more prominent than the enteric symptoms.

Illness usually lasts less than 10 days, but up to 20% of the patients studied in the hospital-based series had a more prolonged and severe illness, with persistently high fever and frequently grossly bloody stools.[207] With bloody diarrhea and abdominal pain being common manifestations, many were thought to have an acute bout of inflammatory bowel disease or a surgical abdomen before *Campylobacter* infection was diagnosed.[206] *Campylobacter* colitis may mimic the early presentation of ulcerative colitis. *Campylobacter* infection may be a cause of exacerbation of inflammatory colitis, but there is no evidence that it plays a role in the etiology of these diseases. Endoscopic examination is often helpful in differentiating infectious from idiopathic types of colitis.[208] Cultures obtained by endoscopy at the site of mucosal ulceration may be positive when stool cultures are negative. *Campylobacter* colitis also may present as a surgical abdomen because of severe abdominal pain or bleeding. In Sweden, 11% of persons with *Campylobacter* enteritis required hospitalization;[209] in Norway, 13.3% of patients were hospitalized.[206]

C. jejuni bacteremia occurs in approximately 1.5 per 1,000 intestinal infections;[210] the rate is highest in the elderly and in immunodeficient persons.[211] In most patients, the bacteremia is associated with diarrhea and other gastroenterological symptoms. In contrast, *C. fetus* bacteremias are infrequently associated with diarrhea. Of all *Campylobacter* bacteremias, 89% are due to *C. jejuni* or *C. coli*; only 8.6% are due to *C. fetus.*[210]

Rarely, *Campylobacter* may infect the biliary tract, giving rise to cholecystitis, pancreatitis, or obstructive hepatitis.[82,212,213] It has been reported to cause splenic rupture.[214] It may cause peritonitis in patients receiving peritoneal dialysis,[215] and occasionally has been isolated from the urinary tract in women. *C. jejuni* infections in pregnant women are likely to be mild and self-limited; however, neonatal sepsis and death can occur if the woman is infected during her third trimester.[216]

A reactive arthritis has been reported after both symptomatic and asymptomatic *Campylobacter* infections.

Similar to *Shigella, Salmonella*, and *Yersinia* infection, this complication is associated with HLA-B27 in about 60% of the cases.[217] In Scandinavia, 1–2% of patients with *Campylobacter* enteritis develop arthritis beginning 4 days to 4 weeks after the onset of diarrhea.[218] Interestingly, in another Scandinavian study, 32 patients in a hospital for rheumatic diseases developed culture-confirmed *C. jejuni* infection during a hospital outbreak; none of these patients developed exacerbations of their existing conditions.[219]

During the past decade, *C. jejuni* infections have been implicated as triggers of the Guillain–Barré syndrome (GBS), an acute demyelinating disease of peripheral nerves. Both serological and cultural studies indicate that 20–40% of GBS patients are infected with *C. jejuni* in the 1–3 weeks before the onset of neurological symptoms.[30,31,220] There is no relation between the severity of gastrointestinal symptoms and the likelihood of developing GBS following infection with *C. jejuni*; in fact, even asymptomatic infections can trigger GBS.

Between 30 and 80% of *C. jejuni* isolates from GBS patients in the United States and Japan belong to LPS (O) type19.[30,221,222,223] This serotype is present in less than 3% of randomly selected *C. jejuni* strains reported to the CDC, and thus is overrepresented in patients with GBS. Antibody cross-reactivity between structures on the cell surface (including *C. jejuni* O:19 LPS) and glycolipids or myelin proteins may explain this association.[224]In South Africa, O-type 41 overrepresented among GBS-associated *C. jejuni* infections.[225]

In addition to sporadic cases of GBS in the United States, Japan, and other industrialized countries, *C. jejuni* infection has been implicated as a potential cause of acute motor axonal neuropathy (AMAN) in China and other developing nations. AMAN is clinically indistinguishable from GBS but affects the peripheral nerve axon and spares myelin. AMAN occurs in epidemics during the summer and fall and principally affects children living in rural areas of northern China.[226] Case–control studies showed that children with AMAN were more likely than controls to have serological evidence of preceding *C. jejuni* infection.[225] Interestingly, patients in the United Kingdom who developed GBS following *C. jejuni* infection also had axonal degeneration.[220]

Other reported but rare postinfectious complications of *C. jejuni* infections include hemolytic anemia, hemolytic–uremic syndrome, carditis, and encephalopathy.[227–229] Erythema nodosum and migrating urticaria also have been associated with *Campylobacter* infections.[79]

Illness due to *Campylobacter* infection is frequently self-limited and usually ends within 10 days; however, one or more relapses can occur. Those with more severe symptoms may have persistence of illness for 1 month or longer. Rarely, *Campylobacter* infection may cause mild, chronic diarrhea.[31,230,231] Illnesses are more likely to be prolonged and more severe in patients with HIV infection.[22,232–234] Among persons with AIDS, *C. jejuni* infections are reported almost 40 times as frequently as in the general population.[23] This excess of *C. jejuni* infections affects only infections in the later stages of HIV disease; patients with early HIV infection and relatively high CD4 counts are not unusually prone to *C. jejuni* infection or relapses of such infections.[235] Hypogammaglobulinemia patients develop severe persistent and relapsing infections due to *C. jejuni*.[236,237] A lack of opsonizing activity also predisposes individuals to bacteremia and other extraintestinal manifestations, including osteomyelitis, cellulitis, and meningitis.[238,239]

The most important principle of treatment of acute gastroenteritis due to *C. jejuni* infection is maintenance of hydration and electrolyte balance. In most cases, this can be accomplished by encouraging oral fluids. Campylobacters are susceptible in vitro to a wide variety of antimicrobial agents.[240] Because erythromycin is safe, easy to administer, and has less of an inhibitory effect on fecal flora than other antibiotics, it is the recommended therapy. However, most clinical trials performed in adults or children have not found that erythromycin significantly alters the clinical course of *Campylobacter* infection.[241–244] Only one study in Peru demonstrated that children with bloody diarrhea benefitted from erythromycin therapy if treatment was begun early in the course of illness.[60] Treatment of susceptible organisms shortens the duration of convalescent excretion, which in areas of poor sanitation may be useful. Other patients who may benefit from antimicrobial treatment include those with prolonged (>1 week) or worsening symptoms, high fevers, or bloody stools. HIV-infected or other immunocompromised persons also should receive antibodies for *Campylobacter* enteritis. Because infection with *C. jejuni* in pregnant women may have deleterious effects on the fetus, pregnant women also should receive antimicrobial treatment for *C. jejuni* infections.

Years of testing for antimicrobial resistance in many parts of the world has demonstrated that the resistance rate to erythromycin among *C. jejuni* isolates has changed very little,[245–248], although there is an upward trend in erythromycin resistance among *C. jejuni* isolates in Thailand[249] and Sweden.[250] At one time it appeared that fluoroquinolones such as ciprofloxacin had emerged as the treatment of choice for *Campylobacter* enteritis in particular and for acute bacterial diarrhea in general.[251] Unfortunately, as the use of fluoroquinolones has expanded (especially in food animals), the rate of resistance of campylobacters to these agents has increased.[252–255] Resistance rates to tetracycline also are increasing, especially

among *C. coli* isolates.[256–258] The newer macrolides, azithromycin and clarithromycin, have excellent in vitro activity against campylobacters[259–261] but provide little clinical advantage over erythromycin and are considerably more expensive.[262] Nearly all strains of *Campylobacter* are resistant to cephalosporins.[263] Gentamicin and imipenem are active against campylobacters, with resistance in fewer than 1% of strains. Therapy with these agents is indicated in persons with bacteremia and other extraintestinal suppurative infections. Because gentamicin is ineffective against *Campylobacter* in the gut, oral therapy also must be given.

8.2. Diagnosis

The diagnosis of *Campylobacter* infection is based on a positive stool culture or a positive blood culture. The frequency of bacteremia was low (about 1%) in one series of patients hospitalized for acute *Campylobacter* enteritis.[264] Not all commercial blood culture methods support the growth of *Campylobacter.*[265]

Serological diagnosis may be useful in industrialized countries where background asymptomatic infection rates are low. Serodiagnostic techniques may also be useful in determining the role of *Campylobacter* in abortion, postinfectious syndromes, inflammatory bowel disease, and other late manifestations of *Campylobacter* infection.

Serotyping and biotyping of *C. jejuni* and *C. coli* have been useful in epidemiological investigations to determine associated cases and the source of infection. Typing as well as PCR techniques for direct detection of organisms has been successful in research studies but has not yet been applied to the clinical setting.

9. Control and Prevention

Because poultry, livestock, pets, and wild animals are the major reservoir for these organisms, control is based on interruption of transmission to humans from animals, animal products, or environmental sources contaminated by animals. Transmission of *Campylobacter* infection to poultry flocks most likely occurs via environmental sources;[217] therefore, careful hygienic practices on farms may reduce contamination of flocks. Awareness of the necessity for hand washing after contact with animals or animal products and the importance of proper cooking and storage of poutry products—indeed *all* foods of animal origin—are as important for preventing *Campylobacter* infections as they are for *Salmonella* infections. Similarly, consuming only pasteurized milk and treated water is an important sanitary measure for the prevention of illness by individuals. The majority of *Campylobacter* outbreaks would not have occurred if not for the consumption of raw milk. HIV-infected and other immunedeficient persons should be particularly careful to avoid high-risk foods (such as unpasteurized dairy products or untreated surface water), as the consequences of infection may be more severe. Because many outbreaks and sporadic cases of *Campylobacter* infection are caused by injection of contaminated water, special care should be taken to prevent contamination of community drinking water supplies with animal or bird excrement or with untreated water. Travelers to developing countries and campers should be cautioned against drinking untreated water. Routine use of antibiotic prophylaxis to prevent infection is not recommended.

Control of nosocomial transmission from patients hospitalized with *Campylobacter* infection is another important consideration. As such "excretion precautions" are recommended for infected infants, children, and adults with fecal incontinence. In general, the bases for control of enteric infection in the hospital are sanitary disposal of excretions and contaminated linens, and hand washing by the patient and by staff members after contact with the patient, especially following contact with excreta. For *Campylobacter* infection, precautions should be maintained for the duration of the illness.

To date, there have been no reports of transmission of *Campylobacter* infection by asymptomatic excretors. Asymptomatically infected food handlers or hospital employees need not be excluded from work, but the need for hand washing after defecation should be stressed to these individuals. Recommendations are different when persons are infected with *Campylobacter* and continue to have diarrhea. Because of the known risk of transmission of other enteric pathogens from individuals with diarrhea, food handlers and symptomatic hospital employees with patient-care responsibilities should not be permitted to work until the diarrheal episode has ended. Because of the diversity of serotypes of *C. jejuni*, the possibility of vaccination for prevention of infection is limited. However, identification of group antigens could make immunization feasible.

10. Unresolved Problems

Epidemiological and clinical research during the last 10 years has done much to define the disease and the sources of infection. The priorities should be directed at public health prevention. First, we must learn how to produce poultry and livestock that are not infected with *Campylobacter*. This strategy would not eliminate *Campylobacter* because of the vast reservoir in wild animals and birds, but

it should decrease considerably the number of human infections. Efforts also should be directed at determining how to process meat so that it is not contaminated with animal feces containing campylobacters.

Cheaper and simpler diagnostic methods should be available so that a greater number of patients can be cultured for *Campylobacter*, which in turn might lead to better surveillance and more opportunities to investigate outbreaks to find additional modes of transmission. Efforts should be made to introduce simple and inexpensive isolation methods into all diagnostic microbiology laboratories. This should be combined with training in isolation techniques for technicians. Research on new diagnostic methods such as simple antigen detection kits and non-radioactive DNA probes should be pursued and a simple, standardized serotyping scheme should be widely available and routinely used.

The role of *C. jejuni* infection in triggering GBS was not understood until recent years. The pathogenesis of this association as well as possible prevention and control strategies needs to be explored. The pathogenesis of *Campylobacter* infection, the host mechanisms that allow most infections to be self-limited, and the occurrence and mediators of immunity are still not well understood. Research in the area of pathogenesis and immunity should continue and may help provide the basis for effective prophylaxis or intervention.

CHAPTER 10

Chancroid

Jaffar A. Al-Tawfiq

1. Introduction

Chancroid is caused by *Haemophilus ducreyi*, a gram-negative bacterium. Chancroid, a genital ulcerative sexually transmitted disease, is characterized by painful genital ulcers and inguinal lymphadenitis. Like other genital ulcerative diseases (GUD), chancroid facilitates the transmission and acquisition of human immune deficiency virus (HIV).[26] The concern over the synergy between HIV infection and chancroid has renewed the interest to understand the pathogenesis of the disease and to develop new diagnostic methods.

2. Historical Background

The first differentiation between chancroid (soft chancre) and syphilis (hard chancre) was made by Bassereau in Paris in 1852.[8] However, it was in 1889 when Augusto Ducrey identified the causative organism by serial inoculation of the purulent material from genital ulcers into the skin of the forearm of three patients.[23] He was able to maintain serial ulcers through as many as 15 generations. However, Ducrey was unable to grow the organism on artificial media. There is controversy regarding the first person who cultured *H. ducreyi* on artificial media; however, the credit has been generally given to Bezancon.[11] Benzacon and colleagues fulfilled the Koch's postulates by experimental inoculation of the organism, infection, and re-isolation of the organism from humans. Later, the name *H. ducreyi* was established in recognition of Ducrey's work.

3. Methodology

3.1. Sources of Morbidity and Mortality Data

The epidemiology of chancroid is not well known because few clinical laboratories perform diagnostic tests, and most of the available data are based on prevalence studies in STD clinics using convenience samples. In addition, culture methods are insensitive and diagnosis of chancroid in developing countries depends on clinical features of the disease. In the USA, the epidemiology of chancroid is described from the data compiled by the Centers for Disease Control and Prevention (CDC).[18] There are no reported fatalities from chancroid since the organism does not cause systemic disease.

3.2. Surveys

There are no meaningful population-based surveys of the presence of previous or subclinical disease. The majority of surveys are done in medical or sexually transmitted disease (STD) clinics.

4. Etiologic Patterns

Haemophilus ducreyi is a fastidious gram-negative bacillus which is a strict human pathogen with no known environmental or animal reservoir.[41] Based on growth requirements, biochemical reactions, and antigenic relatedness, *H. ducreyi* was classified initially in the genus *Haemophilus*.[41] However, rRNA analysis showed that *H. ducreyi* is not found in the Pasteurellacea cluster that includes *Haemophilus* sensu stricto species such as *Haemophilus influenzae* and *Haemophilus aegyptius*.[22] Instead, *H. ducreyi* is found in the *Actinobacillus*

A.S. Evans, P.S. Brachman (eds.), *Bacterial Infections of Humans*, DOI 10.1007/978-0-387-09843-2_10,
© Springer Science+Business Media, LLC 2009

cluster (4B) of the Pasteurellaceae.[21] Biochemically, *H. ducreyi* requires X factor but not V factor for growth, and catalase negative and oxidase positive by the tetramethyl-*p*-phenylenediamine method.[35] *Haemophilus ducreyi* requires an enriched medium containing hemin and serum for growth.[59] The doubling time of *H. ducreyi* ranges from 1.8 to 4 h.[59] The organism usually grows after 48–72 h of incubation at 33–35°C in a high-humid CO_2-enriched environment. The colonies are usually gray to tan, translucent and can be pushed intact across the agar plate. Gram stain of these colonies shows clumping of *H. ducreyi* in long parallel strands with an appearance called "school of fish". The protein profiles and lipooligosaccharide (LOS) structures from various strains of *H. ducreyi* are generally well conserved; however, at least one strain, 33921 has a variant protein profile and LOS structure. Both the whole-cell lysate and the membrane proteins from strain 33921 were found to have altered positions on the gels, both in their apparent molecular weight and pI values compared to the prototypical strain 35000HP. Thus, strain 33921 has been suggested to be a member of a second class of strains, termed class II strains.[48]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

An estimated 6 million cases of chancroid occur yearly worldwide.[54] The epidemiology of chancroid is poorly understood in resource-poor countries with high prevalence of the disease due to the lack of diagnostic tests. Moreover, the epidemiology of chancroid is different between developed and developing countries. In resource-poor countries, the prevalence of chancroid in genital ulcerative diseases ranges between 23 and 56% based on multiplex polymerase chain reaction (M-PCR).[19,58] The incidence of chancroid may exceed that of syphilis as a cause of genital ulcerative diseases in Africa, Asia, and Latin America.[45,50]

In developed countries, chancroid occurs in sporadic outbreaks. In the USA, a total of 54 cases were reported in 2003, reflecting an increase from 38 cases in 2001.[18] However, the overall incidence had decreased from 2.04/100,000 in 1988[16] to 0.02/100,000 in 2002.[18] Most cases of chancroid in the USA were reported among minorities living in urban areas and in the south.[59] *Haemophilus ducreyi* was detected in 20 and 12% of ulcers from patients in Memphis and Chicago, respectively.[40] Similarly, chancroid occurs in sporadic outbreaks in Europe. In a study from Amsterdam, The Netherlands, *H. ducreyi* was detected in 0.9% (3 of 368) of attendees with at a clinic for sexually transmitted diseases [15]

5.2. The Roles of Race and Gender in Chancroid

In outbreaks of chancroid in the USA, *H. ducreyi* infection is more commonly found in African American and Hispanic males than other ethnic groups.[24] In experimental infection with *H. ducreyi*, a multiple logistic regression analysis showed no effect of age or ethnicity on pustule formation rates.[14] However, there were only a small number of observations on African American subjects, which precludes definite comment on the effect of ethnicity on the development of disease.[14]

In natural infections, the male-to-female ratio ranges from 3:1 to 25:1.[41] However, in the human model of *H. ducreyi* infection, males and females develop papules (become infected) at similar rates.[14] However, males develop pustules at a rate nearly threefold that of females, consistent with the epidemiology of natural infection.[14]

6. Mechanisms and Routes of Transmission

Chancroid is a sexually transmitted disease and *H. ducreyi* gains access to the skin through a breakdown in the epithelium. Extra-genital lesions occur secondary to autoinoculation of the organism.[59] Recently, there is a report of three cases of lower-limb ulceration in children caused by *H. ducreyi.* It was postulated that *H. ducreyi* may be a previously unrecognized cause of chronic skin ulceration. Close contact between those children and family members with lower-limb ulceration may have resulted in contamination of skin with wound exudate, allowing *H. ducreyi* to enter via breaks in the epithelium. However, additional epidemiological studies are needed to determine the likely mode of transmission and reservoir for *H. ducreyi* among this population.[61]

7. Pathogenesis and Immunity

7.1. Pathogenesis

Haemophilus ducreyi is highly infectious for humans; however, the infectious dose in natural disease is not known. The estimated rate of chancroid transmission in natural infection is 70%.[47] In the experimental human challenge model, an estimated delivered dose of 1–100 colony-forming units is sufficient to cause disease.[5,14] During the course of chancroid, *H. ducreyi* is found in pustules and in the dermis of experimental lesions.[9] In addition, the organism associates with collagen and fiber and has little association with keratinocytes, fibroblasts, T cells, Langerhans' cells, laminin, or fibronectin.[9] Thus, *H. ducreyi* remains extracellular and

resists phagocytosis. Moreover, *H. ducreyi* is chiefly found within the granulocytic infiltrate and colocalizes with neutrophils and fibrin at the ulcerative stage of disease.[10] In the human model of *H. ducreyi* infection, skin biopsies had an enrichment of T cells and macrophages after 48 h of infection and a neutrophil predominance by 7–9 days.[31] Moreover, macrophages in lesions had high levels of CCR5 and CXCR4 compared with peripheral blood cells.[31] Thus, the presence of up-regulated HIV-1 coreceptors in *H. ducreyi* -infected lesions may explain the increased acquisition of HIV-1 in patients with chancroid.

Many putative virulence determinants of *H. ducreyi* have been tested in the experimental model of human infection by evaluating isogenic mutants. Few mutants of *H. ducreyi* have been found to be attenuated in the human model and include those that did not express the ducreyi serum resistance A (DsrA) protein,[13] HgbA,[4] or peptidoglycan-associated lipoprotein (PAL).[27] DsrA mutant lacks an outer membrane protein, DsrA, and may have been killed by serum transudate in the wound. HgbA mutant may be unable to utilize hemoglobin from extravasated red blood cells and PAL mutant may be structurally unstable.[6] In addition, expression of the LspA1 and LspA2 proteins[32] and an intact *flp* gene cluster[53] are required for the virulence of *H. ducreyi.* The *lspA1 lspA2* double mutant does not inhibit phagocytosis and is attenuated in the human model of infection.[32] *Haemophilus ducreyi* associates with dermal collagen fibers within infected skin lesions and is facilitated by the presence of NcaA, an outer membrane protein.[28] Expression of *H. ducreyi* collagen-binding outer membrane protein NcaA is required for virulence in swine and human challenge models of chancroid.[28] An isogenic mutant of *H. ducreyi* lacking the *ncaA* gene is attenuated in the swine and human models of *H. ducreyi* infection.[28]

On the other hand, other isogenic mutants of *H. ducreyi* were virulent in the model. These mutants include glucosyltransferase mutant, the D-glycero-D-manno-heptosyltransferase mutant and a sialyltransferase mutant.[62,63] A fine tangled pili (FtpA), a hemolysin-deficient, and the major outer membrane protein (MOMP) mutants were also virulent in the model.[3,46,57] The reasons why these mutants were virulent in the human model of infection had been discussed by Spinola et al.[51]

7.2. Immunity

Natural disease does not reliably confer protection against subsequent infections with *H. ducreyi.* Patients had repeated *H. ducreyi* infections during two large outbreaks in the USA.[12,29] Similarly, in the human model of *H. ducreyi* infection, the rates of papule and pustule formation were similar in the reinfection and the naïve groups.[2]

On the other hand, spontaneous healing of an ulcer variant "chancre mou volant" was described in the pre-antibiotic era.[55] Additionally, spontaneous healing of chancroid ulcers was reported in later outbreaks in North America.[12,29] However, the exact mechanism for such healing is not known. In the human infection model, men are more likely to develop pustules, with an odds ratio of 2.8 (95% CI, 1.6–5.0)-fold, than women.[14] In reinfection experiments, some individuals repeatedly resolve all inoculated sites while others repeatedly form pustules.[2,52] These data suggest that some hosts are able to contain the infection with *H. ducreyi*.

8. Patterns of Host Response

8.1. Clinical Features

It is thought that *H. ducreyi* gain access to the skin through a break in the integrity of the epithelium. After an incubation period of 4–7 days, a papule forms and is followed by a pustule within 2–3 days.[49] However, during the course of natural infection, only a minority of patients recall the presence of a papule or pustule at the site of inoculation.[41] Pustules usually rupture 2–3 days later, forming ulcers. These ulcers are usually painful and have irregular edges.[41] The presence of multiple ulcers may occur in one half of patients.[47] If left untreated, chancroid ulcers heal slowly over the following weeks to months.[38] The presence of painful inguinal lymphadenopathy occurs in half of patients with chancroid.[49] These lymph nodes are usually unilateral and become fluctuant and form buboes. Chancroid usually affects the genital skin and mucosa, but may rarely present on extra-genital locations following auto-inoculation and may occur on the inner thighs, breast, or fingers. However, chancroid has not been reported to cause systemic disease. If left untreated, *H. ducreyi* may cause significant tissue destruction and heals slowly over several months with scar formation. Chancroid may lead to phimosis or penile autoamputation.[41] However, *H. ducreyi* has not been reported to cause bacteremia.

HIV-seropositive male patients with chancroid tend to have a greater number of genital ulcers than HIV-seronegative chancroid patients.[60] However, the histopathology of *H. ducreyi* ulcers in both HIV-seropositive and HIV-seronegative patients is identical.[36] More recently, in experimental infection with *H. ducreyi* in 11 HIV-infected persons, the papule and pustule formation rates were similar to those observed in HIV-seronegative historical control subjects. The cellular infiltrate in biopsy samples obtained

from the HIV-seropositive and HIV-seronegative subjects did not differ with respect to the percentage of leukocytes, neutrophils, macrophages, or T cells. Thus, experimental infections in HIV-seropositive and HIV-seronegative persons are clinically similar and do not cause local or augment systemic viral replication.[33]

8.2. Diagnosis

The diagnosis of chancroid is usually based on the clinical features of the disease and exclusion of syphilis and herpes simplex virus. However, in studies that diagnosed chancroid by polymerase chain reaction (PCR) based tests, the clinical diagnosis is neither sensitive nor specific. Gram stain of purulent discharge may show the characteristic trail-road gram-negative coccobacilli. However, Gram stain has a low sensitivity and specificity.[38] Isolation of *H. ducreyi* requires special media and should be incubated in a humid environment with 5% CO_2 at 33–35°C. Generally two media are required for the isolation of *H. ducreyi*.[59] The first medium contains gonococcal agar base, 2% bovine hemoglobin, and 5% fetal calf serum (GC-HgS), and the other contains Mueller–Hinton agar base with 5% chocolated horse blood (MH-HB). These media are supplemented with 1% CVA (ie, cephalothin, vancomycin, and amphotericin B) enrichment or 1% IsoVitaleX to provide L-glutamine and vancomycin.[38] The addition of vancomycin (3μg/mL) inhibits the growth of gram-positive commensal bacteria but may also inhibit the growth of *H. ducreyi*.[34] These culture media are not usually available in all microbiology laboratories and the sensitivity of cultures is about 75% compared to PCR-based tests.[43,44]

Serodiagnosis of chancroid relies on the detection of antibodies directed against whole-cell lysate, lipooligosaccharide (LOS), and a recombinant protein enzyme immunoassay using *H. ducreyi* proteins hemoglobin receptor A (HgbA) and D15. Compared to multiplex PCR (M-PCR), the adsorption enzyme immunoassay has a sensitivity of 53–71% and a specificity of 57–71%.[58] The enzyme immunoassay has a sensitivity of 48±59% and a specificity of 89–90%.[20] The recombinant protein enzyme immunoassay has a sensitivity of 100% and a specificity of 62% compared to M-PCR.[25] However, the main use of serodiagnosis is in seroprevalence studies since antibodies against *H. ducreyi* may persist for months after infection.[20]

Multiplex PCR (M-PCR) is considered the gold standard for the diagnosis of chancroid. M-PCR detects simultaneously DNA targets from *H. ducreyi*, *Treponema pallidum*, and herpes simplex viruses 1 and 2. Routine cultures for *H. ducreyi* have a sensitivity of approximately 75% compared to M-PCR.[42] Unfortunately, M-PCR is not readily available commercially.

9. Prevention, Control, and Treatment

9.1. Prevention and Control

Chancroid is usually very painful and lacks a non-human reservoir, thus *H. ducreyi* infections may be contained in a given population. For chancroid to be maintained in a given population, a high sex partner change rate is required.[54] Thus, chancroid will disappear unless it is present in a highly sexually active population. Multiple strategies have been used to control chancroid outbreaks. In Thailand, a multi-intervention plan that included promotion of condom use and presumptive treatment of commercial sex workers with antibiotics resulted in a 95% reduction (from 30,000 cases/year to less than 2,000 cases/year) of chancroid.[30] In Kenya, syndromic treatment of GUD, condom use, and education resulted in a 78% reduction in GUD in an African mining community.[54] In the human model of *H. ducreyi* infection, a single dose of azithromycin (1 g) prevents the development of infection for up to 2 months after weekly inoculations with *H. ducreyi*.[56] Currently, there is no available vaccine for chancroid. Expression of HgbA is necessary for *H. ducreyi* to survive and initiate disease in a human model of chancroid.[4] Recently, in a swine model of *H. ducreyi* infection, an experimental HgbA vaccine efficiently prevented chancroid. In that study, histological sections of immunized animals lacked typical microscopic features of chancroid, and no viable bacteria were recovered from inoculated sites of HgbA-immunized pigs.[1] Formaldehyde-treated *H. ducreyi* cytolethal distending toxin (HdCDT) elicited toxin-neutralizing antibodies titers 200 times higher than those elicited by the native toxin.[37] However, many studies are needed before a vaccine could be even tested in the human model of *H. ducreyi* infection.

9.2. Treatment

The current CDC recommendations for the treatment of chancroid are as follows: a single dosage of oral azithromycin (1 g), ciprofloxacin 500 mg orally twice a day for 3 days, erythromycin base 500 mg orally three times a day for 7 days, or a single intramuscular dose of ceftriaxone (250 mg).[17] Generally, the cure rate of chancroid with most of these regimens is >90%. The use of a single dose of ciprofloxacin was shown to be as effective as a 7-day course of erythromycin.[39]

Antibiotic treatment failures in HIV-seropositive patients with chancroid have been described for suboptimal regimens even in HIV seronegatives.[60] However,

single-dose azithromycin and ciprofloxacin regimens were shown to have similar efficacy in chancroid regardless of the HIV status of the patients.[7,39] Treatment failures in HIV-infected patients frequently reflect co-infection with herpes simplex virus. Thus, HIV-positive chancroid patients should be followed closely and monitored for co-infection.[17] Sex partners of chancroid patients should be evaluated and treated regardless of the absence of symptoms if they had sexual contact in the preceding 10 days of the patient's symptoms.[17]

10. Unresolved Problems

Some aspects of the pathogenesis of chancroid, especially the early stages of the disease, have been studied in the human model of infection. A recent study showed the localization of *H. ducreyi* in naturally acquired chancroid. However, further studies are needed to determine the relationship between *H. ducreyi* and the host in the ulcerative stages of the disease. Since the organism is extracellular and serum resistance is important for virulence, a vaccine that produces bactericidal antibodies or blocks nutrient uptake could be effective in prevention. The development of vaccines for the prevention of chancroid would have a great impact on the reduction of the rates of chancroid and HIV in areas of high prevalence for both diseases.

CHAPTER 11

Chlamydial Infections

Julius Schachter and E. Russell Alexander

1. Introduction

There are several quite different disease patterns that result from human infection with chlamydial organisms. Infection with *Chlamydia trachomatis* may result in trachoma, a variety of other syndromes that accompany ocular or genital infection, or lymphogranuloma venereum (LGV). *Chlamydia psittaci* has one human disease manifestation—psittacosis. *Chlamydia pneumoniae* causes respiratory disease and infection has been associated with coronary artery disease.

Trachoma causes a cicatrizing keratoconjunctivitis, and its sequelae of keratitis, pannus, entropion, and trichiasis occur in severe form in certain endemic areas, primarily the hot, arid parts of the world. Trachoma is the leading infectious cause of blindness.

From a genital reservoir, *C. trachomatis* is transmitted sexually to cause a variety of diseases (Table 1). In the adult female, disease manifestations include cervicitis, salpingitis, urethral syndrome, Bartholinitis, and postpartum endometritis. In the male, they include urethritis and epididymitis. (Both sexes may contract inclusion conjunctivitis and proctitis.) Infant chlamydial diseases include inclusion conjunctivitis of the newborn, pneumonia, and possibly bronchiolitis and otitis media. In the United States, in other Western countries, and in some developing countries where it has been studied, *C. trachomatis* is the most prevalent sexually transmitted bacterium. In infancy, it is the leading single cause of pneumonia in the first 6 months of life.

LGV is a systemic sexually transmitted disease with worldwide distribution, particularly prevalent in warmer climates. The bubonic form is of declining importance in the United States, although proctitis due to the agent is more often recognized.

Chlamydia psittaci causes an interstitial pneumonia or generalized toxic disease of children and adults that is transmitted from infected avian species. It has become an infrequent disease, except from occupational exposure or exposure to infected psittacine house pets.

Chlamydia pneumoniae causes a range of respiratory diseases from pharyngitis and otitis media to bronchitis and interstitial pneumonia. Clinically and, to a great extent, epidemiologically, the manifestations are very similar to those caused by *Mycoplasma pneumoniae*. From present knowledge it is exclusively a human disease.

2. Historical Background

The description of trachoma is ancient, trachoma being one of the earliest of human diseases to be recognized as a distinct clinical entity.[1] It was described in the Ebers papyrus (1500 BC). The name *trachoma* was first used by Dioscorides in 60 AD, and the stages of the disease were described by Galen a century later. From the Middle Eastern reservoir, it spread throughout Europe in many waves from the time of the Crusades to Napoleon, being known as both "Egyptian and military ophthalmia." In the last century, the disease has decreased in incidence in many of the temperate climates of the world. It has disappeared from Europe, for example, and is essentially gone from foci that existed in the central United States. Although sulfonamide treatment was introduced in 1938, and tetracyclines and macrolides in following decades, they cannot be credited with this change. Rather, it has appeared to follow improvements in the standard of living and of hygiene practices. Trachoma has persisted in hot, dry climates and is still a major cause of blindness in many developing countries.

Table 1. Disease Manifestations of *Chlamydia*

Chlamydia trachomatis			
Trachoma			
Oculogenital diseases			
Adult, male or female:	Adult female:	Adult male:	Infant:
Conjunctivitis	Cervicitis	Urethritis	Conjunctivitis
Proctitis	Salpingitis	Epididymitis	Pneumonia
	Urethral syndrome	Arthritis (Reiter's syndrome)	Bronchiolitis
	Postpartum endometritis		Otitis media
Lymphogranuloma venereum			
Chlamydia psittaci			
Psittacosis			
Chlamydia pneumoniae			
Pneumonia			

In 1907, Halberstaedter and von Prowazek[2] described cytoplasmic inclusion bodies in epithelial scrapings from trachoma cases. They named them "chlamydozoa" or "mantle bodies" because reddish elementary particles appeared to be embedded in a blue matrix or mantle. Two years later, the same investigators reported inclusions in infants with nongonococcal ophthalmia neonatorum. Lindner[3] named this disease "inclusion blenorrhea" and reproduced ocular disease in nonhuman primates from a mother's genital secretion. Inclusions were demonstrated in female genital epithelium and in nongonococcal urethritis (NGU) scrapings. Material from each of these sources and from infant conjunctivitis was used to produce follicular conjunctivitis in monkeys. Thus, it was believed as early as 1910 that trachoma and ocular genital diseases were caused by similar agents, and the vertical transmission of these agents was postulated.

In 1911, Nicolle, Cuenod, and Blaisot[4] in Tunis passed trachoma secretions through Berkefeld V filters and succeeded in producing a conjunctivitis in an ape and a chimpanzee, established to be trachoma by transmission to human conjunctiva. In the 1930s, Julianelle[5] for trachoma and Thygeson[1] for inclusion conjunctivitis expanded these studies with the use of smaller filters. After Bedson had described the unique developmental cycle of the psittacosis agent, Thygeson recognized that the same cycle held true for the agent of inclusion conjunctivitis. Thus, Bedson[6], noting the morphological similarity of the developmental cycles of the agents, termed them members of the psittacosis-LGV group of atypical viruses. This concept was strengthened by the finding by Rake, Shaffer, and Thygeson[7] that they all shared a common complement-fixing antigen.

In the period 1930–1950, the clinical and epidemiological features of trachoma and inclusion conjunctivitis were described[5–8]—all on the basis of cytological morphological identification. In 1938, the first effective therapy of trachoma occurred with the introduction of sulfanilamides, although it was recognized early that these drugs did not kill the agents. In the search for in vitro isolation techniques for Chlamydiae, the chorioallantois of the embryonated hen's egg and a wide variety of tissue-culture systems were explored. These attempts failed, and *Chlamydia* were believed to be a virus with propensity for epithelial growth. Macchiavello in 1944 and Stewart in 1950 claimed organism growth in the yolk sac of embryonated eggs, but their findings could not be confirmed. It remained for T'ang et al.[9] in China in 1957 to clearly isolate the agent of trachoma in yolk sac treated with streptomycin to retard bacterial contamination and to demonstrate that this material caused inclusion-positive conjunctivitis in the monkey model. Collier and Sowa[10] confirmed this finding in African studies in The Gambia and, in addition, showed serological response to the agent in human sera. They also showed that the antigen responsible for seroconversion was common to the psittacosis and LGV groups of agents. An explosion of trachoma research followed, including studies in Saudi Arabia, Egypt, Taiwan, and San Francisco. As the trachoma agent was studied, it became clear that it was not a virus but a small bacterium that shared with viruses the property of obligate intracellular parasitism. The agent of inclusion conjunctivitis was isolated by Jones, Collier, and Smith[11], using yolk-sac techniques. In the period 1960–1980, the development of cell cultures for isolation[12] and microimmunofluorescence methods for antigen identification, immunotyping, and measurement of host response[13–14] has permitted clinical and epidemiological characteristics of *C. trachomatis* diseases to be expanded.

Psittacosis and LGV were first described clinically much later than trachoma [Jüergensen[15] and Hunter[16], respectively], but in both cases their real definition took place in the first half of the twentieth century. The understanding of the biology of the organisms developed more

rapidly than with the trachoma and inclusion-conjunctivitis agents, primarily because of their greater virulence and host range. In particular, their pathogenicity for mice and for the embryonated yolk sac permitted the development of isolation methods and of serological methods (a complement-fixation test was developed as early as 1930).[17] With the advent of tissue-culture methods, the exploration of the molecular biology of Chlamydiae has expanded considerably.[18,19]

Chlamydia pneumoniae disease was first described by Grayston, Kuo, Wang, and Altman.[20] The agent had been recovered from the eye of a primary school child in 1965 in a prospective study of trachoma in Taiwan. Two decades later antibody to this isolate was found in the serum of children and adults with respiratory disease.[20] Saikku's observation that antibody to this organism was associated with coronary artery disease led to a dramatic increase in research on *C. pneumoniae*.[21]

3. Methodology

3.1. Sources of Mortality Data

For none of the diseases caused by *Chlamydia* is there significant mortality, and the rare deaths associated with infant chlamydial pneumonitis or psittacosis are usually in persons with serious accompanying underlying disease. Fatal outcome has no importance in the epidemiology of these conditions.

3.2. Sources of Morbidity Data

Trachoma is not a reportable disease in the United States. For the last 50 years, the World Health Organization (WHO) and many national health agencies have accumulated data on trachoma occurrence by clinical surveys, for planning control efforts, but no continuing statistics on incidence are available. In the United States the genital chlamydial infection is reportable in all 50 states but access to diagnostic tests is not universal and accordingly there is considerable underreporting. Even so, *C. trachomatis* infection is the most common infection reported to the CDC.[22] The WHO considers it the most common sexually transmitted bacterial pathogen, with an estimate of about 90 million new infections each year.[23] Other estimates have been made from sexually transmitted disease clinics where the ratio of nongonococcal to gonococcal disease has been used, along with other prevalence data, to estimate annual incidence.[24,25] LGV is a reportable disease, but because of its rarity, data are usually available only in annual summaries published by the U.S. Public Health Service. Recent awareness of apparent outbreaks of LGV proctitis may change that.[26] Psittacosis is reportable, and data on incidence are published weekly in the *Morbidity and Mortality Weekly Report* and are summarized in *Surveillance Reports* by the Centers for Disease Control and Prevention (CDC). In addition, CDC accumulates data on the occurrence of psittacosis in pet birds or in fowl flocks when these animals are submitted to state laboratories for inspection. There are no data on the incidence of *C. pneumoniae* infections except for small studies done in selected populations. Seroepidemiological studies show that the infection is very common in many countries.

3.3. Surveys

Trachoma-control programs, often supported by the WHO, have depended on clinical surveys of trachoma prevalence and of trachoma sequelae, including blindness. The WHO has helped to standardize survey methods.[27] Most recently, these have been combined with more general surveys of visual acuity and blindness. Traditionally, such surveys do not utilize laboratory diagnostic methods. This is not necessary for trachoma, since the disease is well-defined clinically.

Data on incidence and prevention of genital chlamydial infections are available from research studies. These have included studies in STD clinics, prospective studies in pregnant women, studies of chlamydial genital carriage in normal populations, and surveys in infants.

There are no significant survey data for LGV, psittacosis, or *C. pneumoniae* infections in the United States.

3.4. Laboratory Diagnosis

3.4.1. Cytological Identification. For *C. trachomatis*, the organism can be identified in cytological scrapings or in tissue specimens by recognition of characteristic intracytoplasmic inclusions.[28] Such identification in conjunctival epithelial cells, and less frequently in cervical epithelial cells, constituted the only identification possible from the time when trachoma and oculogenital diseases were first recognized, at the turn of the century, until the organism was isolated in embryonated eggs in 1957.

This diagnostic approach has been supplanted by the use of tissue-culture (TC) isolation methods and by the use of modern nonculture diagnostic tests that detect chlamydial antigens or genes. Study of epithelial cell scrapings stained with Giemsa stain (the time-honored method) may still be

useful for some studies, or when other diagnostic tests are not available.

Cytology is a relatively insensitive way to diagnose chlamydial infection. For many years the most sensitive method for identification of *C. trachomatis* infection of the genital tract was isolation in TC. Antigen detection by direct fluorescent antibody (DFA) staining or by enzyme immunoassay (EIA) are somewhat less sensitive and specific, but are widely used.[29]

Direct methods of detection of chlamydial DNA have not been more sensitive than EIA procedures. However, the introduction of amplified DNA probe technology, such as the polymerase chain reaction (PCR) or ligase chain reaction (LCR), in the mid-1990s, revolutionized chlamydial diagnostics. These tests are highly specific and are more sensitive than any other diagnostic tests, including culture.[30] The broad-based use of nucleic acid amplification tests (NAATs) should provide wide access to accurate *C. trachomatis* diagnosis. The recognition that non-invasively collected specimens (first catch urines and vaginal swabs) can be used in NAATs has opened the door for population-based screening.

Chlamydia trachomatis can be recognized in tissue sections by Giemsa stain, IF methods, and electron microscopy. All these methods have been used in human disease and in experimental models. But here too, the NAATs have replaced these older technology.

Chlamydia trachomatis cannot be recognized cytologically with any consistency in bubo aspirates in LGV using any of the staining methods. Inclusions have been seen in biopsy material, but this is a poor method of identification. Similarly, *C. psittaci* is rarely recognized in cytological preparations and rarely in tissue secretions. FA methods and Giemsa stains have been used effectively in tissue secretions of experimental animal models of *C. psittaci* infection, but are not useful in routine human diagnosis. *Chlamydia pneumoniae* strains are relatively difficult to isolate and have been recovered both from the embryonated egg and from tissue culture. Home-brew NAATs have been widely used in research on *C. pneumoniae* and *C. psittaci* infections, but there are no commercially available tests.

3.4.2. Isolation

3.4.2.1. Chlamydia trachomatis. The method of choice for isolation of *C. trachomatis* is by cell culture. Cells used are McCoy cells, the HeLa-229 cell line, BHK-21 cells, or L-929 cells. A necessary step in cell cultivation of *C. trachomatis* strains other than LGV is centrifugation of the inoculum into the cells. In addition, the cells are treated in some manner to enhance infection; Gordon et al.,[12] who developed the modern cell culture technique, used irradiation of McCoy cells. Cycloheximide has been substituted for irradiation and cycloheximide-treated McCoy cells are the most widely used method at present.[31] Specimen material is inoculated into individual vials with cell sheets on coverslips within them or into wells of microtiter plates that have been implanted with cells. They can be examined at 48–96 h after inoculation. Intracytoplasmic inclusions are recognized by iodine stain, Giemsa stain, or FA techniques. The most commonly used stain is iodine, which permits rapid identification. Iodine stain will only identify *C. trachomatis*. Giemsa staining will permit identification of *C. psittaci* strains in cell cultures, but since this is usually not necessary, iodine stains are most widely used. FA stains will be more sensitive, and can be species or genus specific. The sensitivity of the culture methods is enhanced by one additional passage through cells. LGV strains may be readily isolated in the same system as for the trachoma and oculogenital strains. They grow more readily in cell culture and do not require cell pretreatment or centrifugation.

Isolation of *C. trachomatis* from yolk sac was historically the first method of agent recovery. However, it is far less sensitive than TC, and thus is no longer used. Mouse inoculation is another possible method for LGV isolation. Intracranial inoculation is more effective than intranasal instillation, but both are inferior to yolk-sac inoculation. Trachoma and inclusion-conjunctivitis strains will not grow efficiently in mice.

3.4.2.2. Chlamydia psittaci. These agents will grow in cell culture, in yolk sac, and in mice, by a variety of routes of inoculation. Cultivation in yolk sac or embryonated chick egg is most commonly used in laboratories that are accustomed to this method, as is true of mouse inoculation. This may be accomplished by intraperitoneal, intracerebral, or intranasal inoculation. Since tissue-culture methods are now more widely available because of greater interest in *C. trachomatis* infection, they will be more widely used. In experienced laboratories, the methods have equal sensitivities. Care must be taken with any of these methods when attempting to recover *C. psittaci* strains, since they are more likely to result in accidental laboratory infections and in cross-contamination.

3.4.2.3. Chlamydia pneumoniae. These strains have been isolated from the yolk sac of embryonated eggs, and initially from HeLa cell TC. HL and Hep2 cells have been found to be preferable.[32,33] *Chlamydia pneumoniae* antigen in respiratory tract specimens or isolation systems can be demonstrated with species-specific antibody which is commercially available.

3.4.3. Antigen and Nucleic Acid Probes. In recent years, nonculture diagnostic methods have been evaluated and widely used. The first were direct fluorescent antibody smear (DFA), enzyme immunoassay (EIA), followed by

direct nucleic acid hybridization methods. None of these tests performs nearly as well as the NAATs.

Direct nucleic acid probes are still commercially available, and retain their popularity because they are less expensive than NAATs. They are less sensitive than culture, although they are highly specific.[34] In contrast, the NAAT technology, exemplified by PCR, TMA, and SDA (polymerase chain reaction, transcription-mediated amplification, and strand displacement assay), is far more sensitive than TC and it is extremely specific.[30,35,36] The chlamydial genes can be detected in epithelial cell specimens and in male and female urines.[37–39] The potential for widespread use of noninvasive screening tests is an important option offered by this technology.

All these tests provide ease of transport, automated batch processing, and the ability to diagnose both chlamydial and gonococcal diseases on the same specimen. As with antigen identification methods, there is the drawback that no organism is available for further identification (e.g., serological markers or testing for antibiotic sensitivity). Also, NAATs are more expensive than culture.

3.4.4. Serological and Immunological Diagnostic Methods. *Chlamydia trachomatis*. Although a variety of serological methods have been used in the past, the FA method, first developed by Bernkopf and then by McComb and Nichols, has been simplified and standardized in an indirect microimmunofluorescence (MIF) test by Wang and Grayston. At present, this is the most commonly used test for evaluation of host response to trachoma or to oculogenital *C. trachomatis* agents.[13] For LGV, the complement-fixation (CF) test can be used, although the MIF test remains more sensitive and specific.

The MIF test employs yolk-sac- or cell-culture-grown *C. trachomatis* of all known immunotypes as antigen. Antigen dots are placed on a slide in a specific pattern. They are attached to the slide in a diluted yolk-sac suspension. Serial dilutions of serum, tears, or local secretions are applied followed by fluorescein-conjugated anti-human globulin. An obvious advantage of the test is that the conjugate may be prepared against any immunoglobulin class, thus permitting titration of IgG-, IgM-, or IgA-specific antibody. A counterstain is added to the conjugate to permit clearer identification of specific fluorescence in the dots to which antibody-containing serum has been applied. If differentiation among antibodies to specific immunotypes is sought, the antigens can be evaluated separately. For many purposes, antigen pools can be used.

A CF test is available to measure host response to any chlamydial infection.[40] It is still the most commonly used test for psittacosis and LGV, but it is too insensitive for trachoma or oculogenital infections. Usually, the antigen for the CF is obtained from a yolk-sac-grown LGV strain and is prepared by boiling and treatment with phenol. For *C. pneumoniae* strains, the CF test is intermediate in sensitivity. A CF response can be recognized in approximately one-half of cases showing response by MIF.[20] Many other serological tests have been evaluated and rejected.

For many years, skin-test hypersensitivity to an LGV antigen (prepared from bubo pus) was used for diagnosis of LGV (Frei test).[41] Before more sensitive and specific antibody measurements were available, it was a useful diagnostic aid. However, because cases of LGV are usually not seen early, conversion from negative to positive is rarely observed. In addition, the possibility that positive skin tests merely reflect earlier infections due to other Chlamydiae, along with the relative insensitivity of the test and the difficulty in standardizing antigen, have rendered the test obsolete.

Another immunological method of importance to epidemiological studies is the immunotyping of *C. trachomatis* organisms. Earlier, using a method that employed the protection from type-specific toxic death resulting from massive intravenous inoculation in mice (a method adopted from analogous methods in rickettsial research), it was learned that there were specific immunotypes of *C. trachomatis*. Type-specific immunity could be demonstrated and it appeared that there was some relationship of immunotype to broad disease categories.[42] Wang et al.[13] subsequently showed that a far simpler method of immunotyping could be developed using an MIF method. By this method, 12 immunotypes were shown to be associated with trachoma and oculogenital disease, and another three with LGV. More subtypes have continued to be identified. No such immunotyping method has been rigorously applied to *C. psittaci* but specific immunotypes do exist. For *C. pneumoniae*, only one type has been shown. Immunotyping of *C. trachomatis* strains has no broad diagnostic significance other than the differentiation of LGV and oculogenital strains, but immunotyping can be used as a marker of strains in epidemiological investigations.

With the increased ability to sequence DNA, it is now more common to identify genotypes rather than serotypes.

4. Biological Characteristics of the Organism

Chlamydiae are obligate intracellular bacteria. They were thought to be viruses for many years and were termed *Bedsonia* or *Miyagawanella*. However, it became clear that they had a complex cell wall (similar to gram-negative bacteria in composition), both DNA and RNA, prokaryotic ribosomes, and metabolic enzymes that would permit independent existence, except that they lack energy-production

mechanisms. Moulder[43] has thus termed the Chlamydiae "energy parasites" and credited their obligate intracellular parasitism to this trait.

The other unusual characteristic of the Chlamydiae is their reproductive cycle (Figure 1). The extracellular form of the organism is the elementary body, and it alone is infectious. Following attachment, the elementary body enters the host cell, apparently by a receptor-mediated endocytosis process. If the particles are live, or do not have antibody attached, they prevent lysosomal fusion and replicate in the phagosome. Within 6–8 h of ingestion, the elementary body is reorganized into a reticulate body (sometimes called an initial body). This larger, thin-walled body diverts the host cell's synthetic functions for its own metabolic purpose and proceeds to divide by binary fission. In this stage, the reticulate bodies are not infectious. After 18–24 h, the reticulate bodies become reorganized again into elementary bodies (and thus become infectious again). Subsequently, elementary bodies may disrupt and exit the host cell to infect new cells. The full cycle takes about 40 h for LGV strains, and 72–96 h for the trachoma biovar. These intracytoplasmic collections of elementary bodies constitute the inclusions that may be seen in cytological smears stained by Giemsa or immunofluorescence methods.

Although all Chlamydiae share a genus-specific antigen, there is little DNA homology between *C. trachomatis*, *C. psittaci*, and *C. pneumoniae* strains.[45] The three species of Chlamydiae are distinguished by several features. The elementary body of *C. pneumoniae* is pear shaped with a large periplasmic space, whereas the elementary bodies of the other two species are round with little or no periplasmic space. The inclusions of *C. trachomatis* accumulate glycogen and thus stain with iodine, whereas the inclusions of *C. psittaci* and *C. pneumoniae* do not. The inclusions of *C. trachomatis* are more compact than those of *C. psittaci* and *C. pneumoniae*. A fourth difference is their response to sulfonamides: *C. trachomatis* is sensitive and *C. psittaci* and *C. pneumoniae* are not.

Chlamydia trachomatis can be further subdivided into strains that cause LGV and strains that cause oculogenital infections. They differ significantly in their biological activity. LGV strains (three serotypes) are more invasive and

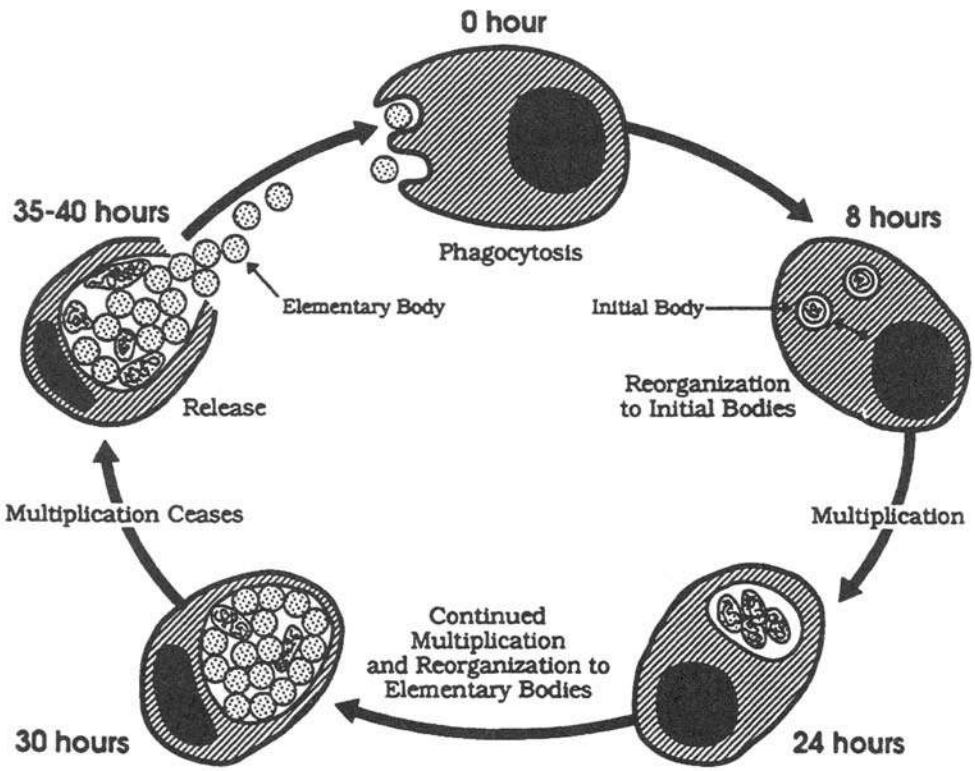

Figure 1. Life cycle of chlamydial organisms. The cycle begins when small elementary bodies infect the host cell by inducing active phagocytosis. During the next 8 h, they reorganize into the larger reticulated initial bodies, which then divert the cell's synthetic functions to their own metabolic needs, and begin to multiply by binary fission. About 24 h after infection, the daughter organisms begin reorganizing into infectious elementary bodies. At about 30 h, multiplication ceases, and by 35–40 h, the disrupted host cell dies, releasing new elementary bodies that can infect other host cells and thus continue the cycle.[44]

can invade many tissues in addition to epithelial cells (e.g., lymph-node invasion, forming the characteristic bubo). This property permits more active cell-to-cell transmission in cell culture and the use of animal inoculation (e.g., mouse) for diagnostic purposes. The oculogenital strains, comprising the trachoma biovar, consist of 12 serotypes. They are not readily invasive in tissue culture and in vivo grow only in columnar and squamocolumnar epithelial cells (conjunctivae, respiratory tract, urethra, cervix, and rectal mucosa).

Chlamydia psittaci will survive for long periods (years) in tissues frozen at –20°C and can persist in dry bird feces for months. Protein (e.g., serum albumin) will aid stability of *Chlamydia*. *Chlamydia trachomatis* strains will lose infectivity within 48 h at room temperature. They are heat-labile, being inactivated in minutes at 56°C. They are inactivated by common disinfectants (e.g., formalin, phenol).

5. Descriptive Epidemiology

5.1. Trachoma

5.1.1. Prevalence and Incidence. Prevalence surveys of trachoma in endemic countries are repeated frequently for control purposes. In hyperendemic areas, the prevalence of trachoma is essentially 100% by the second or third year of life.[46] Active disease, however, is most common in children, who constitute the reservoir of the disease. By adult life, active infection becomes infrequent, although the sequelae of the disease continue to produce the damaging effects that result in visual defect and blindness. In such areas, trachoma constitutes the major cause of preventable blindness.

In areas of moderate endemicity, infection and disease occur later, often beginning at school entry and going through young adult life.[47] The disease is milder in such settings and sequelae are mild, rarely leading to blindness. Often, within such areas, microfoci of severe disease will persist in certain family groups, where a full range of severity will be found.

The United States represents a nonendemic area where trachoma persists only in isolated population segments. As in the hyperendemic areas, this disease status is constantly changing as betterment of living standards results in decreasing prevalence. Thus, in southwestern American Indian populations 40 years ago, 10% of Indian schoolchildren were found to have active trachoma at school entrance.[48] Even as active disease is disappearing, sequelae of trachoma can still be seen in the majority of the older population segment.

5.1.2. Epidemic Behavior and Contagiousness. Trachoma is never seen in epidemic form, although perhaps it could return to susceptible populations under disaster conditions if disruption were to result in marked disturbance of hygienic practices. In hyperendemic areas, it persists and is transmitted by a variety of practices that permit eye-to-eye transmission. This may include the use of common washing utensils or the use of eye drops. The availability of water for washing will greatly affect its transmission. The transmission is potentiated by a variety of ecological factors. In particular, the presence of flies amplifies the transmission of disease. The occurrence of other bacterial eye infections (also transmitted by flies) and the effect of dust on eye irritation also facilitate active infection. When trachoma is reintroduced in nonendemic areas, it is not contagious as long as the hygienic and socioeconomic conditions do not facilitate the transmission.

5.1.3. Geographic Distribution. The trachoma-hyperendemic areas of the world are North Africa and sub-Saharan Africa, the Middle East, drier regions of the Indian subcontinent, and Southeast Asia. Foci of trachoma persist in Australia, the South Pacific, and Latin America.

Within the United States, there are no remaining areas of endemicity. At the turn of the century, there was an endemic focus in the south central United States (extending to Texas). A hospital in Missouri devoted to the treatment of trachoma was closed only in 1950. Similar disappearance of endemic trachoma occurred in Europe, Russia, and the Mediterranean in the same period.

5.1.4. Temporal Distribution. Throughout the world, trachoma has vanished as standards of living improve. Thus, the trends are usually ones of decrease. Within many endemic areas, there are seasonal changes that closely follow the seasonal increase in fly prevalence and the accompanying bacterial conjunctivitis. In some sites (e.g., northern India), two such peaks may occur each year. Such changes will not affect the prevalence of chronic trachoma or the blinding sequelae.

5.1.5. Age. The relationship to age is discussed in Section 5.1.1.

5.1.6. Sex. In hyperendemic areas, there is no sex differential in young children—the reservoir of active trachoma. In adults, reinfection disease occurs more frequently in women taking care of children, and they may also have a higher prevalence of blinding sequelae.

5.1.7. Race. There is no evidence for racial differences.

5.1.8. Occupation. There are no occupational factors that cannot be related to socioeconomic factors.

5.1.9. Socioeconomic Factors. These are predominant epidemiological factors. The important aspects appear to be water availability, fly occurrence, health and hygienic practices, and crowding. Face washing has been identified as

a protective behavior.[49] Studies in Saudi Arabia by Nichols et al.[50] depicted the decrease of trachoma occurring with the creation of small towns replacing rural foci where trachoma had been hyperendemic. Striking differences could be shown among cities, small towns, and oasis villages. In the United States, as in many other countries, trachoma has vanished with improvement in the standard of living.

5.1.10. Other Factors. Although nutritional factors have been questioned as a possible contributing factor, there is no clear evidence that such is the case, and the factors of water shortage, exposure to bacterial conjunctivitis, fly transmission, and the amplifying factor of dust irritation appear to be most important. Jones[46] summarizes these conditions as those that contribute to "ocular promiscuity" (in contrast to the amplifying factors of "sexual promiscuity" for genital *C. trachomatis* infections) (also see Section 6.1).

5.2. Oculogenital Diseases

5.2.1. Prevalence and Incidence. *Chlamydia trachomatis* infections are currently the most common infections reported to the Centers for Disease Control and Prevention (CDC). As of the year 2000, all 50 states and the District of Columbia required reporting of diagnosed chlamydia cases. In the year 2004, 929,462 chlamydial infections were reported to the CDC.[22] This compares to approximately 335,000 cases of gonorrhea being reported to the CDC in that same year. The rate of chlamydial infections in women in the United States increased from approximately 78 to more than 466 per 100,000 of the population in the period 1987–2003. This increase does not actually reflect real increases in infections, but the widening base for chlamydia screening and then more recently in the increased use of nucleic acid amplification tests (NAATs), which are sufficiently more sensitive than other types of diagnostic tests to be responsible for an increased detection rate. The general assumption is that the use of any NAAT will detect about 30% more infections when screening asymptomatic individuals. Forty-four states have chlamydial infection rates greater than 300 per 100,000 of the population. The prevalence in women 15–24 years of age and attending family planning clinics was approximately 6% (range approximately 3–19%). The range reflects differences across states. There have been programs involving the screening and treatment of those who have been found to be infected that have been in place for years, and these programs have had modest effects in decreasing the prevalence of infection in the clinic-attending populations. There is, however, still a relatively high prevalence in the population and in some areas minor increases have been seen. In prenatal clinics, infection rates in 15- to 24-year-old women had a median of 7.4% (range 2–20%).

The infection rate in men is approximately 1/6 the rate that is seen in women. This is largely a reflection of the lack of screening in male populations. Most male infections are diagnosed in symptomatic men, whereas most infections in women are in the asymptomatic.

In 34 states, chlamydia screening is being done in correction facilities. A number of different populations have screening for *C. trachomatis* on an ongoing basis. For example, approximately 20,000 females entering the national job training program have been screened for chlamydia each year since 1990. In 2003, the overall chlamydial prevalence in females entering the national job training program was 9.9%; for men the overall infection rate was 8%.

The introduction of nucleic acid amplification tests and the ability to test non-invasive specimen types have allowed epidemiologists to conduct population-based screening for chlamydial infections. While a fair amount of data has been generated by the CDC, the prevalence of *C. trachomatis* genital infection in the US population at large is unknown. Using urine-based screening, Mertz and colleagues[51] conducted a pilot study as part of the National Health and Nutrition Examination Survey III (NHANES III). The prevalence detected was relatively high in this stratified, multistate probability sample of the US population. Prevalence was 7% in non-Hispanic Blacks and 2% in non-Hispanic Whites. Prevalence was higher in females than in males in all subgroups. In the 15- to 19-year-old women (who represent the highest prevalence populations in essentially all studies), the prevalence was 13% in non-Hispanic Blacks, 11% in Mexican-Americans, and 5% in non-Hispanic Whites.

5.2.1.1. Adult Inclusion Conjunctivitis. No incidence or prevalence data in either males or females are available for this illness.

5.2.1.2. Cervicitis. Overall population estimates for chlamydial infection are difficult to obtain. However, figures have been obtained for different subgroups. Among pregnant women enrolling for prenatal care, 3–25% have been found to be infected, depending on the group examined. In venereal disease clinics,[52] up to 30% of symptomatic women have cervical chalmydiae. The prevalence in asymptomatic partners of males with urethritis may be as high as 50%. In asymptomatic nonpregnant college students, chalmydiae were found in the cervixes of 5%. In screening women in family planning clinics, infection rates have ranged from about 2–3% in higher socioeconomic settings to 30% in inner-city populations. Up to 70% of the chlamydial infections in these settings have been clinically inapparent.[53]

Etiology in cervicitis is more difficult to define, since multiple organisms may be involved. However, chalmydiae

have been isolated from 34 to 63% of women with clinical cervicitis.[52]

5.2.1.3. Salpingitis. In the United States, over 200,000 women per year are hospitalized for active pelvic inflammatory disease, and it is estimated that another million are treated as outpatients. If tubal cultures taken at laparoscopy are regarded as identifying the etiological organism, then *C. trachomatis* causes approximately 20–40% of salpingitis in this country and almost 60% in Sweden, where it has become an uncommon disease.[54] Serological data have also implicated *C. trachomatis* as a causal agent in peritonitis or perihepatitis or both (Fitz-Hugh–Curtis syndrome). Silent salpingitis is more common, and there is evidence that many women with asymptomatic cervical infection actually have upper genital tract disease.[55]

5.2.1.4. Female Urethral Syndrome. The prevalence of acute urethral syndrome is unknown. An estimated 5 million women per year in the United States are seen for symptoms suggestive of urinary tract infection. As many as 30% of these *may* have acute urethral syndrome (acute dysuria, frequent urination, "sterile" urine). Studies in select populations suggest that approximately 30% of the cases of acute urethral syndrome are due to *C. trachomatis*.[52] This has only been shown with young women.

5.2.1.5. Postpartum Endometritis. In one study, seven (22%) of 32 women with *C. trachomatis* cervical infection during pregnancy developed late postpartum endometritis (48 h, 6 weeks postdelivery).[56] In other studies the association has been less or not found.

5.2.1.6. Male Urethritis. In the United States, more than half the estimated 2 million cases of acute urethritis are of nongonococcal etiology. *Chlamydia trachomatis* causes 30–50% of these cases.[57] In some populations, e.g., student health clinics, *C. trachomatis* is far more common than gonococcus as a cause of urethritis.[58]

5.2.1.7. Epididymitis. This severe complication of acute urethritis occurs in approximately 500,000 men per year in the United States. Roughly half these cases are caused by *C. trachomatis*.[58]

5.2.1.8. Arthritis (Reiter's Syndrome). In studies in the United Kingdom, it has been estimated that Reiter's syndrome occurs in about 1% of NGU.[59] An estimate from Finland is 2%.[60] Sexually acquired reactive arthritis (see Section 8.2.1.h) as a complication of NGU without the classic triad of Reiter's syndrome occurs four times more frequently.[47]

5.2.1.9. Infant Inclusion Conjunctivitis and Pneumonia. Approximately 20–30% of infants exposed to *C. trachomatis* in the birth canal will develop conjunctivitis and 10–15%, pneumonia.[52,61] If a conservative figure of 5% maternal carriage rate is used, 3.0 million babies born each year in the United States would yield 45,000 cases of inclusion conjunctivitis and 20,000 cases of chlamydial pneumonia. *Chlamydia trachomatis* has been estimated to cause 20–30% of all pneumonia in infants less than 6 months of age ill enough to require hospitalization.

5.2.2. Epidemic Behavior and Contagiousness. The chlamydial oculogenital diseases behave like other STDs. The increasing incidence and prevalence of chlamydial infection probably paralleled that of gonorrhea, but as gonococcal infection rates have declined in recent years chlamydial infection rates have remained high and may reasonably be termed epidemic at this time.

In the United Kingdom and Sweden, where both gonococcal urethritis and NGU are reportable, the incidence of both diseases rose rapidly from the early 1960s. In fact, the start of the epidemic increase in Sweden preceded the start in the United States by about 4 years. The rest of the curve is very much the same as the United States for gonorrhea. In the mid-1970s, Sweden saw a plateau for the incidence of gonorrhea (the United States experienced the same phenomenon in 1978). In Sweden, the incidence of chlamydial infections has decreased markedly. Chlamydial infections are probably as contagious as gonorrheal infections, but studies to evaluate this have not been done. Reinfections are common, particularly among adolescents. After several years of reduction in prevalence it appears that many regions are experiencing a plateauing, or a slight increase in prevalence of cervical chlamydial infection.[22]

Chlamydia and gonorrhea occur together frequently. *Chlamydia trachomatis* may be recovered from 20 to 30% of men with gonorrhea. Postgonococcal urethritis is now recognized as a chlamydial infection persisting after successful treatment for gonorrhea. Chlamydial and gonococcal infections may occur together in the cervix (35–45% double infection is not uncommon) and inadequate treatment may result in salpingitis.

Chlamydial conjunctivitis may be transmitted from infected persons by contact. There is no evidence that chlamydial pneumonia of infants can be transmitted in any other way than at birth.

5.2.3. Geographic Distribution. The agent and its various clinical pictures have a worldwide prevalence; it has been identified in all populations in which STDs have been examined.

5.2.4. Temporal Distribution. No seasonal variation is recognized.

5.2.5. Age, Sex, Race, Occupation, Occurrence in Different Settings, Socioeconomic Factors, and Other Factors. *Chlamydia trachomatis*, like other genital pathogens, has been found with increased frequency among individuals who are younger, more often nonwhite, unmarried, and of lower socioeconomic status. Both males and

females with infection tend to have had more sexual experience in terms of the number of recent sexual partners. Pregnant women with *C. trachomatis* also tend to be of lower gravidity. These factors also characterize the infants who contract conjunctivitis or pneumonia. No distinctive characteristics of diseased versus nondiseased infected infants have been found. Infant conjunctivitis develops at 5–14 days of life (rarely later to 6 weeks, which may be recurrences). Infant pneumonia develops from 2 weeks to 4 months of age. *Chlamydia trachomatis* pneumonia in older children and adults is rarely seen.

5.3. Lymphogranuloma Venereum

5.3.1. Prevalence and Incidence. Reported cases of LGV have been decreasing in the last few years from 394 in 1974 to 235 in 1994 (the rates have changed from 0.2 to 0.1/100,000 population).[62] The disease is not reportable, and the recent use of molecular techniques to diagnose rectal LGV in homosexual males is not yet reflected in the reported statistics.

5.3.2. Epidemic Behavior and Contagiousness. LGV is transmitted by sexual contact, but the degree of contagiousness has not been measured. Likewise, the epidemic behavior of the disease has not been well documented. The disease was more prevalent in the United States in the first half of this century than it is at present.

5.3.3. Geographic Distribution. In the early part of this century, LGV was more common in the southeastern United States. The present geographic distribution shows a higher prevalence in some of these states (e.g., Virginia, Georgia, and Louisiana). When examined by city, the highest prevalences are in Washington, DC, Atlanta, Houston, and New York. Although some of this concentration can be attributed to better diagnosis in certain centers, it is clear that this also reflects imported disease, particularly in merchant seamen and military personnel. Regarding the source of infection overseas, the disease is more often seen in tropical climates, notably in Africa, Central America, and tropical areas of Asia.

5.3.4. Temporal Distribution. There are no data on temporal distribution.

5.3.5. Age and Sex. This disease is recognized more often in mid-adult life and more often in males than in females.

5.3.6. Race. Although a greater susceptibility of blacks was postulated in years past, such a hypothesis cannot be substantiated, and no difference in racial susceptibility is believed to exist.

5.3.7. Other Factors. The only other population group that appears to be at higher risk are sexually active homosexuals. In recent studies in large cities such as New York, San Francisco, and Seattle, infections have been found among homosexuals, particularly in men with proctitis. However asymptomatic infections are common.

5.4. Psittacosis

5.4.1. Prevalence and Incidence. Psittacosis is a relatively rare disease in the United States. In 1994, 38 cases were reported (0.2/1,000,000 population).[62] Most updated cases are associated with exposure to psittacine birds of domestic or foreign origin. In 2004, only 12 cases were reported.[63] Undoubtedly much of the decrease over recent years is due to the assumption that *C. pneumoniae* is the likely cause of any atypical pneumonia with positive chlamydial serology, except when there is a well-defined avian exposure. Cases associated with poultry processing decreased in the 1970s and then stabilized. An exception was 1984 when a particular outbreak reversed that trend.[64]

All birds entering the United States (except from Canada) are required by the U.S. Department of Agriculture to undergo a 30-day quarantine, during which time they are treated with chlortetracycline. So far, strains remain susceptible to tetracycline. It has been proposed that the quarantine period be extended to 45 days, particularly for larger psittacine birds. The current importation is about 700,000 birds per year.

5.4.2. Epidemic Behavior and Contagiousness. In 1929, epidemic disease from infected psittacine birds spread from Argentina to England, Germany, and the United States as infected psittacine birds were transported to those countries. Discovery of the cause of this disease and its treatment resulted in control of epidemic disease by the 1950s and cessation of such outbreaks. From the 1950s on there were sporadic outbreaks in poultry-processing plants. From 1979 to 1984, there were no significant outbreaks in the United States. In 1984 an outbreak occurred in turkey slaughtering plants, but there have been no outbreaks reported since then.

Human-to-human transmission can occur from a heavily infected pneumonia case, but such occurrence is extremely rare and is of no significance in the epidemiology of the disease. The important epidemiological source remains either psittacine birds or poultry flocks.

5.4.3. Geographic Distribution. There are too few cases to comment here.

5.4.4. Temporal Distribution. The distribution of cases has no distinct seasonal pattern.

5.4.5. Age, Sex, Race, and Occupation. Cases occur more often in mid-adult life and more often in males than in females, reflecting the increased exposure in these groups. There is no evidence of racial predilections. Regarding

occupation, most cases of psittacosis in recent years have occurred in owners of pet birds, employees of the commercial pet bird trade, bird fanciers, pigeon fanciers, and a variety of miscellaneous avian exposures. Since 1974, few cases have occurred in poultry producers and processors, although the potential for such occurrence still exists. Only about 10% of cases occur in persons without clear-cut exposure. Thus, the majority (93% from 1975 to 1984) of cases occur in persons exposed through vocational or avocational activities.[64]

5.4.6. Socioeconomic Factors. Socioeconomic status is not of epidemiological significance.

5.5. *Chlamydia pneumoniae* Infections

5.5.1. Prevalence and Incidence. Pneumonia incidence has been measured in a health maintenance organization in Seattle. The incidence of pneumonia averaged 12 per 1,000 per year. Fifteen percent had *C. pneumoniae* infection, for an incidence rate of 1 per 1,000 per year. This was a little less than half the incidence of *M. pneumoniae* infection. It is thought that the *C. pneumoniae* estimate is a little low as it is based on serology alone.[65] Studies in many countries show that 20–80% of adults have antibody, and in most countries that prevalence is 50% or more.[20]

5.5.2. Epidemic Behavior and Contagiousness. Epidemics have been studied in military recruits in Finland and in one adjacent civilian community.[66] Attack rates varied from 60 to 80 per 1,000 men. The case-to-case interval has averaged 30 days and ranged as high as 3 months. Transmission in all instances is slow, with epidemics lasting as long as 6 months in groups such as military and as long as 3 months for households.

5.5.3. Geographic Distribution. The original isolate was from Taiwan. The most extensive studies have been in the United States, but the prevalence of antibody in adults in most countries studied has been 50% or more. Other countries studied heavily have been Finland, Denmark, Sweden, Canada, Taiwan, and Japan.[20]

5.5.4. Temporal Distribution. The disease can occur in any season. There is some evidence of periodicity, with higher incidence rates of infection for 2 or 3 years followed by 4 or 5 years of low incidence.[65]

5.5.5. Age and Sex. Antibody is uncommon under the age of 5 years, and then age-specific prevalence increases rapidly from 5 to 20 years. Both of these characteristics are similar to the seroepidemiologic findings for *M. pneumoniae*. The prevalence then increases slowly but steadily throughout life. In Seattle, men over 60 years have a prevalence of 70%. Rates are higher in men than in women after the age of 20 years. With current serologic methods there is some loss of antibody with time (3–5 years after the first infection), so that the high rates of antibody after 70 years suggest that virtually everyone is infected at some time in their lives. Reinfections can occur.

5.5.6. Race, Occupation, Occurrence in Different Settings, and Socioeconomic Factors. There are no data that suggest significant differences by race or occupation. The significant excess in males in adult life, as well as the experience in epidemics, suggests that infection may occur more often outside the home in settings such as schools, institutions, and the military.

6. Mechanism and Routes of Transmission

6.1. Trachoma

The conjunctival epithelium of humans constitutes the reservoir of infection for trachoma. It is passed from eye to eye by direct contact. In some instances, this is aided by local practices. For example, in India, it is usual for dye to be applied around the eye, with a small stick or with the finger. This is applied to adult women first and then down to children of both sexes—from the oldest to the youngest. In many Southeast Asian countries, washcloths are applied to the face—again from eldest to youngest, and in crowded areas of poverty, usually the same cloth without a change of water. Both are ideal methods for transmission.

Extraocular infections are known to occur in trachoma endemic areas. The organism can be recovered from throat nasopharnygeal and rectal swabs.[67] It is not known what role such infections may play in transmission of the organism. They are likely to be more important in that they provide a rationale for treatment failures to occur following application of topical antibiotics, as they can be sources of reinfection.

Transmission is also potentiated by flies.[68] They will differ as to species, but in each case they are capable of carrying infected secretions from face to face, where they may be self-inoculated into the eye. Jones[46] showed by the use of fluorescein dyes that ocular discharges could be transferred from person to person in the household in a matter of minutes. He referred to the sum of these various methods of transfer of infected secretions as "ocular promiscuity" and suggested that this characterizes the epidemiological pattern of endemic trachoma in much the same manner as genital promiscuity characterizes the method of transmission for oculogenital diseases. Fly control and provision of latrines are beneficial.[68]

Two other factors play some part in the transmission of endemic trachoma in certain areas of the world—perhaps in preparing the eye for more severe infection. One is the occurrence of other bacterial conjunctivitis—often also fly

transmitted. In certain settings, seasonal epidemics of bacterial conjunctivitis precede the peak of trachoma infectivity by a few weeks. A variety of bacterial pathogens have been implicated, particularly certain *Haemophilus* and *Neisseria* species. It is surmised that the bacterial infections increase both conjunctival and corneal inflammation, and thus amplify their subsequent response to trachomatous infection. Anyone who has been in such areas at the height of the fly season can attest to the intensity of fly infestation. Flies cover the faces of children, particularly around the eyes, where there is conjunctival discharge.

A second set of factors less well understood are the environmental factors that characterize many of the foci of greatest prevalence. These are dust and sunlight—both irritants to conjunctiva and cornea and both hypothesized to aid *C. trachomatis* in its damaging effects. It is difficult to measure these influences, but trachoma remains most prevalent and most damaging in those locations where these factors predominate.[46]

6.2. Oculogenital Diseases

The columnar cells of the adult male urethra and female endocervix are felt to be the reservoirs of infection. Asymptomatic infection seems to be the rule: depending on the type of clinic >50% of infected men and women with positive urethral or cervical cultures have no complaints or discharge. The organism is transmitted via sexual contact.

In women, *C. trachomatis* is responsible for a proportion of acute and chronic cervicitis on examination, but how much is difficult to say, since it is often accompanied by other pathogens. Urethral syndrome or acute urethritis may be a result of simultaneous infection, spread from infected cervical secretions. The organism is responsible for at least 20–40% of cases of salpingitis, presumably via ascending infection. Postpartum endometritis, thought to be at least partly due to *C. trachomatis*, also occurs via direct extension.

In males, the major illnesses (urethritis and epididymitis) are due to direct extension of infection from the primary urethral focus. Hematogenous dissemination has never been documented in either sex. Adult inclusion conjunctivitis is felt to be transmitted via hand-to-eye contact from infected genital foci.

The only documented mode of transmission of infection to infants is vertically by passage through an infected cervix. No hard evidence for transplacental or postnatal infection exists.

6.3. Lymphogranuloma Venereum

The reservoir of infection is the cervix of the asymptomatic female and, to a lesser extent, for the male homosexual, the rectal mucosa of the asymptomatic male. It is spread exclusively by sexual contact. In the male, primary lesions appear on the penis, usually on the glans (occasionally in the urethra), or the wall of the rectum, and in the female on the labia or on the wall of the vagina. Such lesions are usually painless and may be hidden, adding to the risk of transmission. Extragenital sites for primary lesions include hands (especially fingers) and tongue. Although secondary and tertiary lesions are the ones most easily diagnosed and are the stages of disease that result in damaging sequelae, it is the painless primary lesions that are the source for sexual transmission.

6.4. Psittacosis

The predominant sources for human disease are infected avian species, all of which are potential reservoirs. Meyer[69] listed 130 species known to be such sources in 1967, and the list could no doubt be lengthened. The risk of exposure is greatly increased in those occupations in which handling birds or their carcasses is common. The most common avian sources are parrots and parakeets, usually resulting in sporadic cases from pet birds. In recent years, about two-thirds were from psittacine species. Pigeons are another source, as are poultry, particularly turkeys. Wild birds have infrequently been documented as a source. Domestic and other lower mammals are infected with *C. psittaci* strains, but they rarely cause human disease. An exception may be the chalmydiae associated with ovine abortion. These appear to specifically threaten the health of pregnant women. In the overwhelming majority of cases, psittacosis occurs in persons in whom bird processing or handling is a vocation or avocation. Casual exposure is extremely rare.

Transmission between humans can take place, and on rare occasions such transmission has been documented. It usually has resulted from close exposure to extremely sick or fatal cases.

The route of infection is airborne, and the primary site of infection is the lower respiratory tract. The involvement is in the alveoli, with very little evidence of bronchial or upper respiratory tract infection.

6.5. *Chlamydia pneumoniae* Infections

There is no evidence for other than human-to-human transmission of *C. pneumoniae* infection. Clearly epidemics occur, as described in the pneumonia epidemics in military trainees in Finland.[66] Because the organism was originally thought to be a member of the *C. psittaci* species and because it can infect experimental animals, an extensive search for antibody in serum of domestic pets was made and has yielded

no evidence for an animal reservoir. In addition, there is no epidemiological evidence to suggest an unusual frequency of animal contact in cases.[20] *Chlamydia pneumoniae*-like strains have been recovered from horses, koalas, and frogs. It is not known whether these strains have anything to do with human disease. Genomic sequences demonstrate that these strains are quite similar, but not identical to *C. pneumoniae* isolates from humans.

7. Pathogenesis and Immunity

7.1. Trachoma

In the early stages of disease, trachoma appears as a follicular conjunctivitis with hyperemia, edema, and distortion of the vascular pattern of the conjunctiva. This is accompanied by papillary hypertrophy of the conjunctiva. The follicles are, in fact, lymphoid germinal centers. In these initial stages, there is involvement of both palpebral and bulbar conjunctivae. Such conjunctival follicles can occur as a response to a number of stimuli, both infectious and toxic. The infant conjunctiva cannot so respond for a number of weeks, and thus chlamydial ocular infection of the newborn (inclusion conjunctivitis) is afollicular, even though the strains are very similar (e.g., as shown by the disease produced in the experimental monkey eye). The chronic follicular conjunctivitis of trachoma heals by scarring. These scars lead to distortion of the lids. This, in turn, results in inability of the lids to close completely, allowing dust particles to damage the cornea. Similarly, the lid distortion results in trichiasis, or inversion of lashes, which adds to the trauma to the cornea. Both these sequelae of trachoma contribute to blindness.[46] The incubation period is not known. In volunteer studies and experimental studies in the nonhuman primate it is 5–12 days.

Acute corneal involvement includes follicles, which often ring the limbus and, after rupture, lead to corneal defects termed Herbert's pits. Punctate erosions of the cornea occur (epithelial keratitis). Inflammatory infiltrates of the cornea may be seen. A characteristic feature of trachoma is the vascularization of the cornea, with swelling of the corneal–scleral border, which constitutes pannus. This is an important component of trachoma diagnosis.

Collectively, these features of trachoma constitute the acute and chronic conjunctivitis and their blinding sequelae. The occurrence of these features in all populations increases with age, although the age at which they occur will depend on the intensity of disease in each sample.

All these changes have been reproduced experimentally in the monkey, but never with the initial infection, which produces only acute follicular conjunctivitis leading to minimal scarring. Pannus is only a result of reinfection (exogenous reinfection or endogenous relapse).[20] Whether this is true for human disease has never been substantiated. If it is, then the disease that is characterized as trachoma (with pannus) is never a primary infection. Nevertheless, it is clear in human disease that the serious sequelae that lead to blindness occur only as a result of many reinfections, or persistent infection and high infectious load.[70,71]

It has been postulated that hypersensitivity reaction to specific *Chlamydia* heat shock proteins may be responsible for the inflammation seen on reinfection.[72]

If reinfection is a necessary factor for severe trachoma, what is the role of immunity? In the experimental animal, after infection, for a short period, there is immunity to reinfection with homologous strains (but no immunity to heterologous rechallenge). In the few studies that were made with what are now recognized as relatively crude and antigenically weak vaccines, there was transient immunity to rechallenge. When this immunity waned, not only were the experimental animals susceptible to reinfection, but also the severity of disease produced by such rechallenge was enhanced (a phenomenon similar to that seen in other early and crude experimental vaccines, such as those for *M. pneumoniae* and respiratory syncytial virus). Whether such a period of hyperreactivity exists in natural human infection has not been determined, but immunity in nature is fleeting. Infection in humans and in experimental animals produces both local and circulatory immune responses, but these antibodies do not appear to be protective. One epidemiological fact continues to kindle interest in the prospect of producing an effective vaccine for trachoma—the observation that in all endemic situations studied, active trachoma decreases with age. Although the age at which this occurs will vary with the intensity of disease in the population, eventually the older segment of the population no longer has active disease, suggesting that immunity eventually prevails. This occurs at an early enough age in some populations that one cannot attribute it to decrease in ocular promiscuity alone. It is the aim of proponents of vaccine development to create a vaccine that would mimic the natural occurrence.

7.2. Oculogenital Diseases

There are several useful unifying principles in regard to the oculogenital infections caused by *C. trachomatis*: (1) the organism infects superficial columnar epithelial cells in various sites (endocervix, urethra, epididymis, endometrium, salpinx, conjunctiva, nasopharynx, lower respiratory tract) and appears to have little propensity for invasion of or destruction of deeper tissue. (2) The clinical features of

chlamydial infection seem to be produced by the host inflammatory response, rather than by the inherent destructiveness of the organism. (3) *Chlamydia trachomatis* infections may be present and asymptomatic ("latent" or "silent" infection) for prolonged periods of time. For example, infants have been documented to shed organisms from conjunctivae for up to 2 years postdelivery. Similarly, women with cervical infection have been culture positive for over 15 months. (4) The stimuli that convert latent infection to chronic disease, or that determine symptomatic versus asymptomatic primary infection, are unknown. (5) At least in some cases (pregnant women), infection can occur, recur, and persist even in the presence of serum antibody. Cell-mediated immune responses (as measured by lymphocyte blastogenic response) appear to be associated with clearing infection, although the evidence is far from clear.

The incubation periods for oculogenital syndromes vary with the syndrome. Urethritis appears to have an incubation period of 5–14 days. This is longer than the incubation period for gonococcal urethritis, which is 2–7 days. When they occur as a result of concurrent exposure, the chlamydial urethritis usually occurs later, which accounted for the entity known as postgonococcal urethritis that occurred in some cases of gonococcal urethritis treated with penicillin only. The incubation period for cervicitis is probably the same as urethritis, but because of the slow and infrequent development of symptoms, is harder to define. The incubation period for chlamydial salpingitis is longer usually following cervical infection by 2–3 weeks. The incubation period for conjunctivitis of infants, children, or adults is 5–12 days. In the case of ophthalmia neonatorum, chlamydial ophthalmia most often has onset in the second week of life as opposed to gonococcal conjunctivitis which occurs characteristically in the first week. Chlamydial pneumonia of infancy has onset between 3 and 12 weeks of age. From prospective studies it appears to follow the earliest recognition of posterior nasopharyngeal infection by a week or so. Rectal shedding is rarely discovered before the second month of life.

In all illnesses so far studied, the surface chlamydial infection appears to produce an early polymorphonuclear inflammatory response at the surface and a later subepithelial infiltration of lymphocytes, plasma cells, monocytes, and eosinophils. Inclusions have been seen in cervix, conjunctiva, salpinx, and infant airways. Although the antigen load, in terms of inclusions seen, does not appear great, the immune response appears to be profound. In infants with chlamydial pneumonitis, for example, large interstitial and peribronchiolar lymphoid infiltrates and organizing nodules with germinal centers can be seen; these are the "infiltrates" seen on chest radiography.

The preliminary evidence available indicates that chlamydial infections may produce chronic sequelae. The observations are not unexpected, since the intense inflammatory response produced by chlamydial infection can lead to tissue destruction, fibrosis, and scarring. Data from Sweden suggest that chlamydial salpingitis has a higher postinfectious incidence of involuntary infertility and ectopic pregnancy than does gonorrheal disease. Distal tubal obstruction has been reproduced in the nonhuman primate by repeated salpingeal infection.[73] Furthermore, obliterative bronchiolitis has been observed in the lung biopsy specimen taken from an infant recovering from chlamydial pneumonitis.

7.3. Lymphogranuloma Venereum

The primary lesion of LGV is usually painless and may often be missed. The incubation period is variable and has been described as 3–30 days. The primary lesion may be a papule, an ulcer or erosion, a vesicle, or a urethritis. Rarely, the site may be extragenital. Pathologically, there is nothing specific about these lesions. Proctitis commonly accompanies primary anorectal infection.

In most instances, it is the secondary lesions that bring the disease to medical attention. These are involvement of lymph nodes, producing the characteristic bubo. The bubonic form occurs in males more often than females (9:1), in part due to differences in lymphatic drainage patterns. Both inguinal and femoral node chains can be involved (when both are involved, the characteristic groove sign results—a groove between the two chains). Systemic signs (fever, myalgia) may occur at this time, but leukocytosis is rare. Large mononuclear cells proliferate within the nodes and foci become necrotic. These foci may proceed to suppuration and rupture of the nodes, developing draining fistulas. Alternatively, the nodes may spontaneously harden and then heal. In approximately 5% of cases, a chronic lymphadenopathy may occur, which may persist for many years.

What are sometimes referred to as tertiary lesions of LGV is analogous to the sequelae of trachoma in that they are the result of scarring. They include strictures of the rectum and vagina and fistulas that may be rectovaginal or may involve the urethra. These lesions are characterized by destruction of mucosal epithelium with scarring and plasma cell infiltration. Extragenital involvement may rarely involve the conjunctivae, the skin (e.g., fingers), and the oral mucosa—each with respective lymph-node involvement. Even less frequent are syndromes of meningitis, salpingitis, arthritis, and pneumonitis.

LGV elicits a marked host response. Nonspecifically, this is reflected in a hypergammaglobulinemia that may

result in a reversal of albumin/globulin ratio. Specifically, broad and intense response can be measured with chlamydial antigens. For that reason, CF antibodies are uniformly elevated, and this generally insensitive test is useful in this disease, utilizing *C. psittaci* antigen. Using specific MIF antigens, a brisk response is noted, which is characteristically broad (responding to many *C. trachomatis* antigens). Although the immunological response can be readily measured, less is known concerning immunity in this disease. Reinfection has not been reported, but chronic disease can occur. Cellular immunity is poorly studied in this infection, but skin-test reactivity and the prominent tissue damage in lymph nodes suggest that such immunity is operative.

7.4. Psittacosis

The respiratory tract is the organ of entry and initial multiplication. The incubation period is between 6 and 15 days (rarely longer). In the experimental monkey, initial respiratory infection is followed by regional lmphadenopathy (tracheobronchial lymph nodes). Bacteremia occurs, followed by involvement of the reticuloendothelial system with early hepatic infection and persistent splenic infection. Monocytic and polymorphonuclear infiltration of the tracheal wall marks the initial respiratory lesions, but in human specimens from fatal cases, bronchiolar involvement is not found. The characteristic lesion of psittacosis is a serofibrinous alveolar exudate that results in focal or lobar consolidation. The alveoli contain both fibrinous red cells and polymorphonuclear cells. In later stages, alveolar septal-cell hyperplasia with phagocytic infiltration occurs.

The splenomegaly results from lymphoid infiltration with an increase in mononuclear phagocytic cells. Focal necrosis and granulomata may occur in the liver. CNS involvement occurs infrequently and is characterized by congestion and edema of the brain or spinal cord.

Host response to *C. psittaci* infection can be measured in a number of ways, and it is clear that both circulating and cellular immune responses occur. On the other hand, there is no evidence for lasting immunity in either animal or man following this infection. Reinfection is well documented, as is persistent infection under some circumstances.

7.5. *Chlamydia pneumoniae* Infections

The pathogenesis of *C. pneumoniae* infections is not understood. There have been no lung biopsies, deaths, and there is no truly useful experimental model. Our knowledge is limited to clinical observation and the analogy to *M. pneumoniae* pneumonia. The incubation period for *C. pneumoniae* infection is not known. The case-to-case interval averages 30 days. Reinfection has been documented, even in the same epidemic.[66]

8. Patterns of Host Response

8.1. Trachoma

8.1.1. Clinical Features. The initial response to infection with *C. trachomatis* is a conjunctivitis. This involves both palpebral and bulbar conjunctivae, and in both areas, congestion and edema are the first responses, with papillary hypertrophy prominent in the palpebral conjunctiva. This is followed by follicle formation (except for infants less than 6 weeks of age, in whom follicle formation is not possible). Follicles can also be found on the bulbar conjunctiva. Those that form on the limbal border are most characteristic. After rupture, they leave shallow scars, which are termed Herbert's pits. In hyperendemic trachoma, severe disease is more characteristic of the upper tarsus. The conjunctivitis produces an ocular discharge that is initially serous, but with congestion can become serosanguinous. Since trachomatous conjunctivitis is usually a subacute process, necrosis is minimal, and therefore pure trachomatous disease is not particularly purulent (with the exception of infant conjunctivitis, which has either purulent or mucopurulent discharge). Unfortunately, in hyperendemic areas, bacterial infection often accompanies the initial disease, and thus the discharge is often very purulent. In trachoma, corneal involvement is usually present, producing punctate erosions of the epithelium with cellular infiltrates of the central corneal epithelium and anterior stroma (keratitis). Particularly characteristic of hyperendemic trachoma is a neovascularization (pannus) at the superior limbus. This sign is an important component in the diagnosis of trachoma.

In either classic trachoma or adult inclusion conjunctivitis, the most damaging aspects of the disease are the sequelae of reinfection. Follicles of the palpebral conjunctiva scar, which results in distortion of the lids. This may result in trichiasis (inturning of the lashes to scrape the cornea) and entropion (distortion of the lid margins secondary to scarring, resulting in failure of the lids to close, in turn resulting in disturbance of the protective cleansing action of the lids and therefore further corneal scarring, particularly in dusty environments). These changes, along with the recurrent keratitis, in company with multiple reinfections and bacterial superinfections result in loss of visual acuity and may result in blindness.

All these changes are seen, but to a lesser degree, in adult inclusion conjunctivitis. The difference in sequelae between trachoma and inclusion conjunctivitis is probably related more to the greater number of reinfections in hyperendemic trachoma and the adverse physical environment (including the effect of fly-borne bacterial conjunctivitides) than it is to the biological difference between trachomatous and oculogenital chlamydial strains. When reinfection has been studied in nontrachomatous environments [e.g., the studies of Mordhorst et al.[74] in Denmark], each of the sequelae of trachoma has been recognized, but in lesser severity.

8.1.2. Diagnosis. Epidemiologically, trachoma is recognized in restricted areas of the world (see Section 5.1.3) and within those areas can most often be found in populations with poor hygiene and under conditions that favor "ocular promiscuity" (often also favoring fly-borne bacterial conjunctivitis). Other isolated population segments in nonendemic countries may have endemic trachoma.

According to WHO[27] definitions, the clinical diagnosis of trachoma can be made if two of the following signs are present: (1) lymphoid follicles on the upper tarsal conjunctiva; (2) typical conjunctival scarring; (3) vascular pannus; and (4) limbal follicles or their sequelae—Herbert's pits. Scales of severity and activity have been used to classify trachoma. The most commonly used staging is called the MacCallan classification, which progresses from immature follicles (I) to mature follicular disease (II), active follicles with scarring (III), and scars and other sequelae without activity (IV).

For epidemiological survey purposes, Dawson et al.[75] have devised a scale of intensity based on three gradations of follicle activity and papillary hypertrophy. For the potentially disabling irreversible lesions, simple three-grade scores for congenital and corneal scarring and for trichiasis or entropion or both have also been devised. This method leads to more reproducible and epidemiologically valid results in surveys.

Other syndromes can cause follicular conjunctivitis, including viral and bacterial infections, toxic follicular conjunctivitis, vernal catarrh and atopic conjunctivitis (allergic in origin), and a variety of rarer forms of chronic follicular conjunctivitis of unknown etiology.

The laboratory diagnosis of *C. trachomatis* infection in trachoma is best made by NAATs. In the past it depended on the recovery of *C. trachomatis* from conjunctival scrapings or the demonstration of characteristic inclusions in the cytoplasm of conjunctival epithelial cells obtained from such scrapings. These may most easily be recognized with Giemsa stain, but DFA methodology is more sensitive.

An advantage of the Giemsa stain in cytological diagnosis is the recognition of the characteristic inflammatory response. Whereas viral conjunctivitis usually elicits a lymphocytic response, and vernal catarrh and atopic conjunctivitis can be recognized by the presence of eosinophils or granules, the characteristic picture in trachoma or inclusion conjunctivitis is a mixture of polymorphonuclear leukocytes, immature lymphoid cells, and plasma cells. Also, Leber cells (giant macrophages containing ingested material) are often seen. This inflammatory response, while not in itself diagnostic, may aid in the cytological diagnosis of trachoma.

Although antibodies to *C. trachomatis* may invariably be recognized in the sera of trachomatous patients by MIF methods, it is unusual to detect an antibody rise, since the disease is most often recognized in its chronic state and therefore reflects only past infection with a *C. trachomatis* strain.

8.2. Oculogenital Diseases

8.2.1. Clinical Features (see Table 1)

8.2.1.1. Adult Inclusion Conjunctivitis. Adult inclusion conjunctivitis in both the male and the female is an acute follicular conjunctivitis with edema, mucopurulent exudate, and erythema. Inclusions can be found on scrapings of either the tarsal plate or the lower palpebral conjunctiva, and chalmydiae can be cultured from either site. Infection is thought to occur from infected genital tract secretions via hand-to-eye contact. The illness is self-limited, although treatment will shorten the clinical course. Progression to trachoma has not been documented, but pannus and conjunctival scarring may result from reinfection.

8.2.1.2. Cervicitis. Chlamydial infection of the endocervix is often associated with a purulent endocervical discharge, congestion, and inflammation. The essential finding is the presence of mucopus (discoloration) on a cervical swab. Initially the criterion of 10 or more polymorphonuclear leukocytes per microscopic field was also used, but the difficulties of standardizing the smears made this unreproducible. A more reliable criterion, in addition to mucopurulent exudate, was bleeding induced by swabbing the endocervical mucosa (friability of the mucosa).[76] More than 50% of women with chlamydial cervicitis are asymptomatic, but many may have an abnormal cervical appearance. The difficulty in diagnosing chlamydial cervicitis is that the findings present are often the same as those found with cervicitis of other etiologies. Furthermore, the cervix is often infected with several other organisms simultaneously.

Under the proper stimulus (as yet undefined), chlamydial cervicitis may progress to salpingitis, or to postpartum endometritis in pregnant women, and it may be associated

with urethral syndrome. Endometrial infection has been shown to follow cervical infection in more than one-third of cases.[77] An inflammation of Bartholin's gland may also be caused by *C. trachomatis*. Without progression to other sites, chlamydial cervical infection may remain active but silent, or it may be cleared by the host either spontaneously or with treatment.

8.2.1.3. Salpingitis. Chlamydial pelvic inflammatory disease is similar in presentation to that caused by other organisms, with the exception that it tends to be of more gradual than acute onset and to exhibit low-grade fever, and often has elevation of the erythrocyte sedimentation rate (>30 mm/h). Like gonorrheal illness, it tends to occur in younger, more sexually active women, and as a first rather than recurrent episode. Major signs and symptoms include fever, lower abdominal pain, and adnexal and uterine tenderness on pelvic examination. The diagnosis of chlamydial infection has proven difficult, however, since the organism may reside solely in the salpinx. Thus, cervical or cul-de-sac cultures may yield gonorrhea or anaerobes, yielding a false diagnosis. The clearest results have been obtained in Sweden using laparoscopy with tubal biopsy,[54] but this is neither a universally available nor an accepted technique for mild illness. The contribution of chlamydial salpingitis to involuntary infertility and to ectopic pregnancy in the United States is not known, although both have increased in parallel with increase in the incidence of salpingitis. Assuming 1 million cases of salpingitis per year in the United States and 15–20% resulting in bilateral tubal occlusion, it has been estimated that 150,000–200,000 women per year become infertile as a result of salpingitis—at least one quarter of which can be attributed to chlamydial infection.[78]

An uncommon complication of salpingitis is perihepatitis (Fitz-Hugh–Curtis syndrome), assumed to be caused by peritoneal spread of the infection. Studies have implicated *C. trachomatis* as etiological agent in a proportion of these cases.

8.2.1.4. Female Urethral Syndrome. This syndrome is the equivalent in women of NGU in men. It is predominantly manifest as frequency dysuria, with sterile pyuria on microscopic and cultural examination, in young, sexually active women. In this specifically defined group, one study revealed a 62% (10 of 16) prevalence of *C. trachomatis* as the etiological agent.[79] Other studies show a lesser contribution. Often, there is a history of a new sexual partner in the month prior to symptoms. Untreated, the urethral syndrome will resolve with time. Long-term sequelae are as yet undetermined.

8.2.1.5. Postpartum Endometritis. Chlamydia trachomatis cervical infection in pregnant women has been associated with the development of postpartum endometritis, with onset more than 48 h after delivery in approximately one-third of cases.[56] The disease is not different clinically from that due to other organisms.

8.2.1.6. Male Urethritis. Chlamydial infection of the adult male urethra is the most common single cause (30–50%) of "nongonococcal urethritis" (NGU) or "postgonococcal urethritis." This is a syndrome of dysuria with or without discharge, with pus cells on Gram smear of an endourethral swab, in which *Neisseria gonorrhoeae* can be neither seen nor cultured. The disease occurs in young, sexually active males and is at least equal in prevalence to gonococcal urethritis in the United States. Untreated, it may lead to epididymitis or resolve spontaneously. Treatment shortens the clinical course.[57]

8.2.1.7. Epididymitis. Chlamydia trachomatis is the most common cause of "idiopathic" acute epididymitis in sexually active man under 35 years of age with no underlying genitourinary pathology.[58] The prevalence of the organism in the urethra, semen, and epididymis of these men far exceeds that of *N. gonorrhoeae*, coliforms, or *Pseudomonas* species. Patients with chlamydial epididymitis tend to have a more chronic course, with more induration of the epididymis, than those with other etiological diagnoses. The illness will resolve spontaneously, although treatment hastens recovery. The incidence of infertility following chlamydial epididymitis is unknown. However, chlamydial epididymitis is often associated with oligozoospermia.

8.2.1.8. Arthritis (Reiter's Syndrome). One of the most serious complications of NGU is Reiter's syndrome. Symptoms appear 1–4 weeks after onset of urethritis. The arthritis is usually asymmetric, involving large joints of the lower extremities or sacroiliac joints. In most patients, arthritis may be the only manifestation. Achilles tendon and plantar fasciae may also be affected. This condition has been termed sexually acquired reactive arthritis (SARA). The full expression (termed Reiter's syndrome) may additionally involve eyes, skin, and mucous membranes. Ocular involvement ranges from a transient mild conjunctivitis to severe uveitis. Skin lesions may involve the penis (balanitis) and a keratoderma of the palms and soles. The mucous membrane lesions are small ulcers of the palate, tongue, and oral mucosa. Symptoms eventually will cease, even without treatment, but recurrences are common.[59] Other infections (not sexually transmitted), such as *Shigella* and *Salmonella*, can also cause Reiter's syndrome.

Chlamydia trachomatis has been recovered from the urethra of at least one-third of cases of SARA, but serological evidence suggests that one-half to two-thirds are a result of this infection. Antibody responses are much higher than are usually seen in NGU, suggesting that a brisk immunological response is a part of the condition. A genetic predisposition to the development of SARA is marked by

the presence of histocompatibility determinant HLA-B27 in two-thirds of cases. Additional evidence for *Chlamydia* etiology comes from examining synovium or synovial fluid cells with fluorescein-labeled monoclonal antibody to *C. trachomatis* and demonstrating elementary bodies in the joint.[80]

8.2.1.9. Infant Inclusion Conjunctivitis. Inclusion conjunctivitis of the newborn is by far the most common cause of neonatal conjunctivitis in the United States and is estimated to be 10 times as prevalent as gonococcal ophthalmia neonatorum.[81] Approximately 25% of infants born to cervix-positive mothers will develop some degree of chlamydial conjunctivitis, involving one or both eyes. The illness most commonly has an incubation period of 1–3 weeks. Infants then present with varying degrees of conjunctival erythema, edema, and mucopurulent discharge. Physical examination shows a *nonfollicular* conjunctivitis (as distinct from the conjunctival disease of older children and adults) with diffuse erythema of the conjunctivae. Fever and systemic findings are absent. Untreated, the disease course is quite variable. Generally, the conjunctivitis remits within 3–4 weeks, although asymptomatic shedding may persist indefinitely. Occasionally, re-exacerbations may occur for unknown reasons. Chronic sequelae do occur; in one study, micropannus was observed in a small percentage of infants 1 year following infection.

8.2.1.10. Infant Pneumonia. Chlamydia trachomatis pulmonary infection has been estimated to cause 20–30% of all hospitalized pneumonia in infants less than 6 months old.[81] Approximately 10–20% of infants born to cervix-positive mothers will develop pulmonary disease. These infants typically present between 3 and 12 weeks of age, although younger patients have been seen. They have a history of chronic congestion and of a chronic staccato, machine-gun-like cough.[82] They are usually afebrile, with minimal malaise, but may have a history of poor growth and weight gain. On examination, they tend to be congested and tachypneic and to have diffuse rales on physical examination. Conjunctivitis is sometimes present. Laboratory examination characteristically reveals eosinophilia (>300–400/mm^3), hyperglobulinemia (especially IgM), and elevated antichlamydial antibody titers. Chest radiographs show hyperexpanded lungs with variable degrees and patterns of infiltrates. The organism itself may be cultured from nasopharynx, tracheal aspirate material, or lung biopsy, if obtained. Although pneumonia is best studied, other forms of lower respiratory tract disease can occur (e.g., bronchiolitis).

Untreated, the illness tends to be chronic, with multiple exacerbations and remissions, but with gradual recovery over weeks to months. Although placebo-controlled therapy trials have not been performed, appropriate antibiotic therapy does eliminate shedding of the organism and probably shortens the course of the illness.

8.2.2. Diagnosis. The major epidemiological features of chlamydial genital diseases are that they occur in predominantly younger, more sexually active adults who are more often single, of lower socioeconomic status, and more often nonwhite. This is the pattern expected in a sexually transmitted disease. Infant disease may be expected in a proportion of those born to infected women.

In all of the syndromes listed below, NAATs would be considered the diagnostic tests of choice.

8.2.2.1. Adult Inclusion Conjunctivitis. The diagnosis is suspect if a follicular conjunctivitis is present. Wright- or Giemsa-stained conjunctival scrapings will reveal inclusion-containing epithelial cells if done carefully and examined in an experienced laboratory. Similar diseases are caused by bacteria (including *Neisseria meningitidis* and *N. gonorrhoeae*) and viruses (especially adenovirus). Bacterial conjunctivitis is usually purulent, without follicles.

8.2.2.2. Cervicitis. Clinical features include mucopurulent discharge, ectopy (redness), with edema, friability, and congestion. Laboratory diagnosis is difficult, at best, since a positive chlamydial endocervical swab or paired serological fourfold titer change is required. Wright- or Giemsa-stained cervical scrapings examined for inclusions are not generally helpful. Other organisms associated with a similar picture include *N. gonorrhoeae*, *Mycoplasma hominis*, herpes simplex, and possibly *Trichomonas vaginalis* and *Ureaplasma urealyticum*. The presence of mucopurulent exudate is most frequently associated with chlamydial or gonococcal infection.

8.2.2.3. Salpingitis. Epidemiological and clinical features are discussed in Section 8.2.1.c. Laboratory diagnosis is most definitively made with tubal culture of biopsy under laparoscopy. Endometrial culture has the best correlation with tubal infection. Other sites in which chalmydiae may be cultured with less reliability include cervix and pelvic cul-de-sac. Serologically, a fourfold or greater rise in antichlamydial antibody is usually demonstrable.

Other agents associated with salpingitis include *N. gonorrhoeae*, gram-negative enteric organisms such as *Escherichia coli*, and anaerobic flora.

8.2.2.4. Female Urethral Syndrome. Diagnosis of chlamydial etiology is, first, by exclusion of other bacterial etiology on urine and urethral culture and, second, by the culturing of *C. trachomatis* from the urethra or cervix. Other etiological agents include coliforms, staphylococci, and possibly ureaplasmas.

8.2.2.5. Postpartum Endometritis. Information on this syndrome is still limited. However, diagnosis may be

established by obtaining *C. trachomatis* from endometrial curetting, aspirates, or swabs. The diagnosis is suspect if *C. trachomatis* is obtained on cervical culture. A serological change also occurs in this infection. Endometritis is also caused by *N. gonorrhoeae*, coliforms, and anaerobes.

8.2.2.6. Male Urethritis. Diagnosis is similar to that of urethral syndrome, except that in this case gonococcal infection must be ruled out. Other known causes of NGU include *U. urealyticum* and *Mycoplasma genitalium*.[83] In 20–30% of cases, no agent is isolated or serological conversion demonstrated.

8.2.2.7. Epididymitis. Diagnosis is made by exclusion of bacterial agents in urine, urethra, or epididymis (coliforms, *Pseudomonas*, *N. gonorrhoeae*) and by culture of *C. trachomatis* from urethra or epididymal aspirate, or both, or demonstration of seroconversion.

8.2.2.8. Arthritis (Reiter's Syndrome). In either SARA or Reiter's syndrome, the diagnosis is made by recovery of *C. trachomatis* from the urethra of a clinically compatible case or the demonstration of a fourfold rise in specific antibody, or both. Alternatively, the presence of IgM *C. trachomatis* antibody, or the presence of high titers of IgG antibody, is presumptive evidence of chlamydial involvement.

8.2.2.9. Infant Inclusion Conjunctivitis. NAATs are the tests of choice, but conjunctival scraping (stained by Giemsa or FA methods) or culture for *C. trachomatis* are also useful procedures. Gonococcal ophthalmia neonatorum and other bacterial agents may be excluded by culture and Gram smear. Chemical conjunctivitis (silver nitrate) rarely presents as late as chlamydial disease.

8.2.2.10. Infant Pneumonia. Diagnosis of chlamydial disease is made with a compatible clinical history and physical examination, eosinophilia, hyperinflation, and hyperglobulinemia, coupled with a positive tracheal aspirate, nasopharyngeal, or lung biopsy culture. Serological diagnosis using paired sera may be accomplished retrospectively in patients on antibiotics who are culture negative.

Since this disease occurs early in infancy, active infection may be suspected with a high titer of specific IgG antibody (particularly if it is simultaneously compared with maternal titer) or by a high titer of specific IgM antibody ($>$1:32 by MIF).[84]

Agents that cause similar pictures are *Bordetella pertussis* and *Bordetella parapertussis*, cytomegalovirus, respiratory syncytial virus, and adenovirus. Recent evidence has also suggested *Pneumocystis carinii* as an etiological agent.

Another potential diagnostic problem is differentiation from lymphocytic interstitial pneumonia (LIP) associated with human immunodeficiency virus (HIV) and Epstein–Barr virus (EBV) infections. Usually they do not occur at the same age. *Chlamydia trachomatis* pneumonia is rare after 4 months of age and LIP is rare before 6 months of age, characteristically occurring in the second year of life. Tachypnea, rather than repetitive cough, is characteristic of LIP and the radiographic pattern is more diffuse in LIP. Although both may have hyperglobulinemia, eosinophilia is not characteristic of LIP.

8.3. Lymphogranuloma Venereum

8.3.1. Clinical Features. The primary lesion of LGV may develop on the penis, labia, vagina, or cervix, or within the urethra, anus, or rectum, often resulting in proctitis. Rarely, it may be extragenital (e.g., fingers or tongue). Since it is usually painless and may be papular, ulcerative, or bullous, it rarely will cause the patient to seek medical attention, and is usually not recognized historically. The secondary lesion of LGV consists of lymphadenopathy, which may follow the primary lesion in 1–6 weeks. With genital involvement, either inguinal or femoral lymph-node chains may be involved, starting with a single node, but progressing to involve the whole chain. Abscesses form within the nodes, which expand to necrotic foci that may become fluctuant, spontaneously rupture, and leave chronic draining fistulas. These necrotic abscessed nodes are the buboes that characterize this disease—and are most commonly the initial recognition of it. The fact that a far greater number of males than females are recognized to have buboes (up to 10-fold in some reports) probably reflects the anatomical differences in lymphatic drainage from the various sites. The vaginal and cervical infections often drain to retroperitoneal chains, as do the anorectal primaries, which may produce manifestations more often confused with appendicitis or inguinal hernia. In the bubo stage, fever, myalgia, and headache may reflect systemic response to the lymphatic infection, and leukocytosis may result. Buboes may spontaneously subside and should not be surgically incised or drained, but may be aspirated. Rarely, chronic lymphadenopathy may result from this disease. The tertiary stage of disease consists of chronic inflammation and scarring, which may result in stricture and fistulas. These changes may follow acute LGV by 5–10 years. Urethral strictures may occur, as may penile fistulas. Anal strictures and rectovaginal fistulas are more often the sequelae in females (perhaps because of the more silent involvement of retroperitoneal lymph nodes). The current increase in the incidence of anorectal LGV in male homosexuals in the United States may be expected to result in increased recognition of resultant anal strictures due to tertiary LGV in the future.

In 2003, an outbreak of rectal LGV was reported in The Netherlands. Similar cases were soon identified in other countries in Western Europe and North America. These infections were detected through the use of nucleic acid amplification procedures. Sequencing of the chlamydial genes found that the cases in The Netherlands were due to a previously unrecognized genovariant of L2.[85]

There has been considerable concern about the sudden appearance of rectal LGV in these communities because the disease is quite invasive, ulcerative, and theoretically it could result in an enhanced HIV transmission or acquisition.

It has been questioned that whether there is, in fact, a new LGV outbreak, with a new strain. The likelihood that LGV is actually endemic at low levels within these communities has been raised.[86] This conjecture is based on the fact that the regularly used diagnostic procedures for *C. trachomatis* infection of the genital tract will not differentiate between LGV and infections with the trachoma biovar. Only through the use of more specific methods to identify genomic variations were these infections identified as LGV. However, the clinical condition of LGV proctitis has been recognized for decades, what appears to be a unique genovar of L2 was found to be a common type seen among isolates from rectal specimens from men with proctitis in San Francisco in the 1980s.[87]

Much rarer clinical manifestations reflect unusual extragenital sites of primary infection, such as axillary buboes with finger sites or submaxillary buboes for oral lesions. Other rare reported manifestations of LGV include meningitis, arthritis, pneumonitis, and conjunctivitis.

8.3.2. Diagnosis. Epidemiologically, LGV is found in sexually active persons, particularly those with past histories of other STDs. At one time, it was prevalent in blacks in the southern United States, but this is probably no longer true. Since the disease is more prevalent in African and Southeast Asian countries, another epidemiological feature of the occurrence in the United States has been overseas contact, such as is found in port cities or in returning military personnel who have served in these areas. In recent years, however, the disease has been found more frequently in the more sexually active male homosexual population in the United States. This segment probably represents the most frequent source of infection in the United States today.

Clinically, the primary lesion rarely comes to medical attention, and the most commonly recognized stage is that of the bubo. They are most often recognized in males, and then by inguinal or femoral node chain involvement. If both chains are involved, the "groove sign" is seen, the groove being formed between enlarged nodes of both chains. Although highly characteristic of this disease, it is seen in only 15–20% of cases.

The differential diagnosis of LGV includes syphilis (although characteristically the nodes are hard and separate in that disease), granuloma inguinale, and chancroid. Other causes of lymphadenopathy such as various viral infections or cat-scratch disease can often be differentiated by the discrete and often tender adenopathy they produce and more usually involvement of other chains of nodes. Herpes genitalis may present with lymphadenopathy. Bacterial lymphadenitis may mimic LGV, but sites of invasion should be recognized, and, of course, in these instances, bacteria will be recognized in node aspirates. Lymphoma and leukemia are also a part of the differential diagnosis.

The laboratory diagnosis is most definitively made by NAAT or by tissue culture of bubo aspirate. However, if the node is necrotic enough to rupture spontaneously, it may be too late to recover active organisms. (In the past, yolk-sac culture or mouse inoculation was used for diagnosis, but tissue-culture methods are more sensitive.)

The Frei antigen—a skin test made of a partially purified elementary body suspension of yolk-sac-grown LGV—was used widely for diagnosis but it is not available in the United States today. However, cell culture isolation and serological methods have supplanted the Frei test. The poor sensitivity and specificity and the delay in development of the latter test have made it obsolete.

As with other chlamydial infections, the definitive serological method is the MIF method. However, in the case of LGV, as with psittacosis, CF antibodies usually result from infection within a few weeks of the initial infection and characteristically result in high titers ($>$1:64). The CF test is group specific and may be performed with either LGV or psittacosis yolk-sac- or cell-culture-prepared antigens. Although cross-reactions with the oculogenital trachoma strains would be expected, the general insensitivity of the CF test results in few patients with the oculogenital syndromes who have detectable CF antibody, and then usually at low titer.

8.4. Psittacosis

8.4.1. Clinical Features. The most common human manifestation of infection is an atypical pneumonia. It may be a relatively mild systemic disease (like mycoplasmal pneumonia) or a more severe one (like influenza). An alternative presentation is an acute septic-like illness with fever and chills and little pneumonitis. Liver and spleen enlargement may occur (particularly in the latter toxic form). Without treatment, fever may extend into the second week, and before chemotherapy, the case-fatality rate averaged 20%, being higher in those 50 years of age and older. With

apparent recovery, relapse may occur later —sometimes a matter of years following the original infection. In the 1,136 cases reported in the United States in 1975–1984, pneumonia occurred in 54%.[64] Other common symptoms are headache, weakness, and myalgia. Rarely, manifestations such as arthralgia, meningiomas, abdominal pain, photophobia, pleuritis, or pericarditis may result.

8.4.2. Diagnosis. Serological diagnosis is most often employed. The CF test (insensitive for trachoma or oculogenital disease) is sensitive enough for this disease. The usual criterion is a fourfold increase in titer from acute to convalescent sera, but single titers above 1:64 are highly suggestive. *Chlamydia psittaci* can be isolated in yolk sac in embryonated eggs, in mice, or in tissue-culture systems. The best source for isolation is sputum or bronchial aspirate. Whole blood (heparinized or citrated), serum, or plasma may occasionally yield the agent. Isolation is more common in the second week of disease.

8.5. *Chlamydia pneumoniae* Infections

8.5.1. Clinical Features. The limited observations to date suggest that *C. pneumoniae* organisms cause a range of respiratory disease from pharyngitis and otitis media through bronchitis to pneumonia.[20,65] Illness is more frequent in school-aged children and young adults. It is also apparent that the majority of infections are of low-grade manifestation or are asymptomatic. There appears to be some tendency for more severe manifestations to be seen in the adolescent or young adult. In general, the disease is mild. Onset of illness is gradual and symptoms are often extended over a number of weeks. In all these characteristics, *C. pneumoniae* disease is very similar to *M. pneumoniae* disease.

Pharyngitis (often with laryngitis) appears to precede lower respiratory disease in most cases, often by a week or more, and often gives the impression of a biphasic illness. By the first clinic visit an average of 13 days has elapsed from the onset of symptoms and the patient is often afebrile. Sinusitis is more often present than in *M. pneumoniae* infections. Chest findings are common on auscultation at this stage. With lower respiratory tract symptoms, the chest radiograph almost always demonstrates pneumonia. There is commonly a single subsegmental lesion, although more extensive involvement is sometimes found. Of pneumonia patients, 84% were outpatients.[65] In hospitalized patients, three retrospective serologic studies have found 6–10% of community acquired pneumonia to be due to *C. pneumoniae* infection.[20] In this study there were no clinical or radiologic features that differentiate this etiology. In this setting the mean age was in the sixth decade and there was often preexisting chronic illness. This reflects the finding that the disease is commonest in youth, but more severe in the elderly. Bronchospasm and the onset of asthma have recently been associated with *C. pneumoniae* infection, but these findings need to be corroborated.[88]

Many research studies have shown an association between *C. pneumoniae* infection and atherosclerosis. The original observations were seroepidemiologic studies that found high titers of antibody to *C. pneumoniae* in atherosclerotic patients. The seroepidemiologic data associating *C. pneumoniae* infection with coronary artery disease led to a very broad-based research approach attempting to associate *C. pneumoniae* infection with atherosclerosis. Many studies found that the organism was present in coronary artery plaque. This was demonstrated by a number of different procedures including PCR, in vitro hybridization, cytology, electron microscopy, and isolation of the organism from atherosclerotic tissue. Animal models showed that *C. pneumoniae* infection could induce lesions in arteries or could speed the development of these lesions in animals selected for the ability to develop such lesions due to dietary or hereditary considerations.

A number of relatively small trials of antibiotic treatment suggested that antichlamydial therapy had a beneficial effect in preventing the development of secondary coronary events. However, more definitive studies using either azithromycin or gatifloxacin that were well powered to detect the efficacy of antibiotic treatment for prevention of secondary coronary events failed to confirm results of the smaller studies. The risk reduction was essentially negligible in these large studies that involved many thousands of patients. Thus, at this point one would consider that routine antibiotic treatment for *C. pneumoniae* for the prevention of secondary coronary events is not indicated.[89]

However, it must be stated that the failure of antibiotic treatment to prevent secondary coronary events does not prove or disprove the hypothesis that *C. pneumoniae* causes coronary artery disease. It is likely the only way to prove that hypothesis would be if an effective vaccine were to be developed and an appropriate long-term trial could be done to actually prevent *C. pneumoniae* infection and allow such infection to develop in a placebo-vaccinated group. There are several theoretical reasons why the antibiotic treatment following the coronary event would not be beneficial even if *C. pneumoniae* were the cause of the disease. First, it is possible that the role of C. *pneumoniae* is in early-stage disease and not late-stage disease. Second, it is not clear that these drugs which do have an antibacterial effect on the organisms in vitro, perhaps even in epithelial cells, would have the same efficacy in treating infection *in situ* (presumably, in histiocytes or macrophages).

The response to antibiotics is not striking. In vitro studies show maximum sensitivity to tetracyclines and erythromycin. Maximum levels of antibiotics are needed for prolonged periods, usually for at least 14 days. New longer acting macrolides such as azithromycin show promise, but there have been no controlled trials reported.

There are a number of other diseases that researchers have claimed, or speculated, are caused by *C. pneumoniae.* But because of the very high infection rate and the high prevalence of antibodies it is very easy to demonstrate *C. pneumoniae* infection in essentially any disease one would like to study. It does not mean that there is either a specific association or a causative relationship between that infection and the disease. Thus, it has been difficult to understand many of these claims. This combined with the problems in diagnostic tests and reproducibility from laboratory to laboratory, and one winds up dividing the literature into those who are believers and those who are non-believers.[90]

One area where this is clearly true is the area of neurologic disease due to *C. pneumoniae*. A number of studies have shown that the organism is present in the central nervous system. Whether this actually reflects true infection of the brain, for example, or whether it is an incidental finding or an epiphenomenon associated with chlamydial infection of blood vessels in the brain is certainly not clear. There are studies suggesting that *C. pneumoniae* could cause multiple sclerosis and Alzheimer's disease. While positive results have been reported from more than one laboratory for both of these conditions it is far from clear that there is any etiologic relationship.

8.5.2. Diagnosis. Isolation of *C. pneumoniae* has been difficult because the organism failed to adapt readily to commonly used cell cultures for other Chlamydiae. The use of HL cells has improved this situation.[32] The organism can be isolated from respiratory specimens, but the yield from pharyngeal specimens (often all that is available) is not great. Lower respiratory tract specimens yield better results. A major problem in understanding chlamydial diseases caused by *C. pneumoniae* is the lack of sensitive, reproducible diagnostic tests. There are many home-brew NAAT procedures that have been used and none of them have taken the lead as the test of choice. This lack of standardization has a corollary and that is lack of reproducibility. Some laboratories have found certain procedures easy to do and report having successful results with demonstration of the organisms quite easily. Others try the same procedure with negative results. The ultimate question is, are those who claim success actually getting true positives; or are they dealing with false-positive results or laboratory contamination; or are those who report negative results actually failing to perform these assays in the correct way and thus getting poorer results? This has been a particular problem with PCR tests, where results are highly divergent.[91,92] The serologic test of choice is the micro-immunofluorescence (MIF) test and it is highly dependent upon the expertise of the reader and is not a procedure that is easily mastered. It has become the standard test for serology. There are commercially available serologic kits whose performance is uncertain. Even with MIF, this test in the best of hands fails in the most crucial aspect of the diagnosis of chronic infection. For acute infections, fourfold seroconversions and high IgM titers are markers of recent infection. The choice of a single high titer as an indication of acute infection is in fact a compromise for epidemiologic purposes, and it is not proof of acute infection at all. IgA antibodies, because they are short-lived in other settings, have been proposed by some as markers of chronic infection, but other studies have found that IgA antibodies are largely a trailing indicator of IgG and thus are not markers for either acute or chronic infection. The bottom line is that there is no simple way of diagnosing a chronic infection.

The micro-immunofluorescence test (MIF), developed for *C. trachomatis* is the only sensitive and specific test available, and is useful for serologic studies.[14] The test is demanding and is available in only a few research and commercial laboratories. Two patterns of response have been described. The first is one of slow development of IgG and IgM antibodies over 1–2 months, with subsequent loss of IgM antibody. This would appear to be a primary type of response. The second pattern is one of rapid IgG response in the absence of any IgM response and is more often noted in older individuals. This is more characteristic of a secondary or reinfection response.

Complement-fixing (CF) antibodies are not specific among *Chlamydia* species. The test is often used for the diagnosis of psittacosis. In the absence of good epidemiologic evidence for *C. psittaci* infection, a positive CF test is more likely to be due to *C. pneumoniae*. CF antibody response is found in two-thirds of patients in whom a primary response MIF pattern can be measured. No CF antibody is measured in reinfection pattern sera. Thus CF antibodies may be useful in screening for primary infection (particularly in younger patients). They are not useful in the diagnosis of reinfections or for seroepidemiologic studies.

9. Control and Prevention

9.1. Trachoma

9.1.1. General Concepts. Elimination of trachoma has occurred in large segments of the world, not as a result of specific control programs, but following the changes in

lifestyle that accompany a raised standard of living. However, in those areas of the world where trachoma remains hyperendemic, such changes are not likely to occur soon. Therefore, much national and international effort has been expended (with significant contributions from the WHO) on trachoma control programs. In the last few decades, trachoma control programs have been based almost entirely on the mass application of locally applied antibiotics. The results have been far from encouraging. After initial response, trachoma returns to become endemic again.

Recognition that community-wide treatment with azithromycin could dramatically reduce the prevalence of chlamydial infections has revolutionized our approach to trachoma control.[93] A single dose of azithromycin has become the treatment of choice for genital chlamydial infections and was shown to be effective in treating trachoma cases. Community-wide treatment has been incorporated into a control program that is aimed at the ultimate elimination of blinding trachoma as a public health program by the year 2020. The International Trachoma Initiative (http://www.trachoma.org) has been organizing this program with massive support from the manufacturer of azithromycin who has been donating all of the antibiotics and private charitable organizations, non-governmental organizations (NGOs), and the WHO. The program is based on what is being called the "SAFE" strategy:

- S—Surgical repair of lids already damaged by trachoma to prevent the future development of blindness
- A—Community-wide treatment with Azithromycin in trachoma endemic areas.
- F—Facial cleanliness to minimize the transmission of *Chlamydia* after the prevalence of infection has been reduced by antibiotic treatment.
- E—Environmental improvements, also aimed at minimizing the transmission of *Chlamydia* through the provision of latrines (aimed at controlling flies) and safe water supplies.

9.1.2. Antibiotic and Chemotherapeutic Approaches. Community-based antibiotic treatment programs with oral azithromycin treat both ocular and extraocular chlamydial infection, and those with clinically active trachoma, as well as asymptomatic carriers.

9.1.3. Immunization. Soon after *C. trachomatis* was first recovered in eggs, laboratories in London, Boston, and Taipei (later Seattle) began developing vaccines for trachoma.[47] Even though reinfection can readily occur in humans following prior trachoma, it was found in monkey models that hyperimmunization with vaccine could prevent reinfection, at least under the somewhat artificial environment of an animal trial. In one instance, a similar result was obtained in blind volunteers. However, each of the candidate vaccines was made with relatively crude whole-organism preparations, and all of them gave only fleeting protection. Even more discouraging was the finding that both in animal experiments and in human trials, subsequent rechallenge might result in more severe disease than occurred in rechallenge after natural infection (a phenomenon that has also been seen in other experimental vaccines of low antigenic potency). At that point, all vaccine trials were abandoned, pending further study of the molecular biology of the organism, with the hope of discovering antigenic subunits that might result in a more permanent immunity. Such efforts are about to move from the laboratory bench to animal testing.

9.2. Oculogenital Diseases

9.2.1. General Concepts. Since these are STDs, control measures are similar to those for gonorrhea and syphilis. *Chlamydia trachomatis* should be sought by culture or antigen detection methods in persons with STD complaints or history. Current recommendations include treatment of all persons with urethritis (gonococcal or nongonococcal), mucopurulent cervicitis, pelvic inflammatory disease, and epididymitis in men under age 35 years as if they had both gonococcal and chlamydial infection.[58] They should be treated with a penicillin-like antibiotic (or alternative where penicillin-resistant strains exceed 3%) and a tetracycline antibiotic (or erythromycin in pregnant women). Other individuals recommended for *C. trachomatis* treatment are asymptomatic contacts to patients with the four syndromes mentioned above and others with established gonococcal or chlamydial infections. Similarly, sexual partners of persons with gonococcal infection should be treated. All of these could be treated without a positive laboratory test if diagnostic laboratory sources are limited. Then diagnostic screening can be saved for highest risk groups. Current recommendations are that all sexually active women between ages 16 and 25 years should have annual tests for chlamydial infection.[58] Those found to be infected should be retested more frequently (3–4 months interval). When possible, contact tracing should be pursued. Both cases and contacts should be treated concurrently and should avoid intercourse (or use condoms) during treatment. In pregnant women, culture and treatment are indicated to protect against postpartum maternal and neonatal consequences.

9.2.2. Prophylaxis. In infected males and nonpregnant females, treatment with azithromycin or doxycycline eliminates infection and therefore provides prophylaxis against the complications of that infection.[58]

Treatment of women during pregnancy or immediately postdelivery will eliminate infection and may protect against postpartum fever and endometritis. Furthermore, for the

treatment to be effective during pregnancy, the sexual partner must be treated simultaneously to prevent reinfection. Azithromycin is considered the drug of choice (1 g oral). If further study elucidates prenatal fetal or maternal complications of infection, or both, routine first-trimester cervical culture and treatment of positive women and partners may be a theoretically useful prophylactic procedure.

For infants, effective prevention of chlamydial disease occurs by treating mothers and partners prior to delivery.[94] Silver nitrate prophylaxis is ineffective against Chlamydiae; topical erythromycin or tetracycline eye prophylaxis at birth for the prevention of inclusion conjunctivitis may reduce it somewhat, but are not highly effective and will not prevent pneumonia.

Antibiotic resistance of *C. trachomatis* has not been shown and is not currently a clinical problem.

9.2.3. Immunization. No immunization for oculogenital diseases is available.

9.3. Lymphogranuloma Venereum

9.3.1. General Concepts. Prevention of LGV depends on the recognition and treatment of infected persons. Problems exist in both these aims. Although classic cases of LGV are easily recognized, relapse of old disease may occur, particularly in debilitated persons. Furthermore, the occurrence of relatively silent disease in anogenital carriers, particularly in sexually active homosexuals, and the difficulty in availability of simple diagnostic tests result in rather persistent endemic foci. For LGV, unique among other chlamydial diseases, a specific highly effective method of chemotherapy is also lacking. Sulfonamides were classically used, but more commonly today, tetracycline therapy is preferred. The major difficulty is in assessing the effect of therapy, particularly in treatment of the embryonic or tertiary stage.

9.3.2. Prophylaxis and Immunization. No prophylaxis or immunization for LGV is available.

9.4. Psittacosis

9.4.1. General Concepts. Control of psittacosis depends on control of avian sources of infection. Control of the 1929 pandemic of psittacosis was accomplished by bans on the importation of psittacine birds. This was followed by a method of certification of clean flocks, but many of these efforts were damaged by poor supervision, smuggling, and contamination of susceptible birds from clean flocks during shipment. An effective method for controlling psittacosis in parakeets has been developed—a chlortetracycline-impregnated seed. Current requirements for quarantine of imported birds are for 30 days of treatment. This is probably not enough, and it has been proposed that this be extended to 45 days. It is probable that some birds have suppressed infections that reactivate during shipment following quarantine. The remaining problems are ones of assuring more adequate response to control regulations.

The control of occupational disease in the poultry-processing industry appears to have been successful in recent years, although there is no developed public health program. The epidemics in 1974 served to alert the industry to the problem, and the infection in poultry flocks tends to be rapidly recognized and treated. It is also probable that human disease continues to occur, but is quickly recognized, treated, and not reported in these workers.

9.4.2. Prophylaxis and Immunization. There is no prophylaxis in humans, and although experimental psittacosis vaccines have been developed in birds, they are not cheap enough to replace antibiotic treatment of birds. There is no need to develop human vaccine for such an infrequent disease.

10. Unresolved Problems

10.1. Trachoma

For trachoma, there is no problem of diagnosis, since clinical recognition is relatively simple. Effective treatment is available. A vaccine would be useful, but development of one depends on a greatly expanded understanding of the immunology and molecular biology of this agent.

10.2. Oculogenital Diseases

10.2.1. Epidemiology and Disease Spectrum. There have been no significant additions to our knowledge of the disease spectrum in recent years. Syndromes such as otitis media, prostatitis, diarrhea, or pharyngitis have not been shown to be caused by *C. trachomatis*. Reports that claimed to find a significant contribution of *Chlamydia* to pharyngitis were based on serological evidence. It is now clear that this phenomenon and the unexplained increment of antibody in early childhood were both a function of cross-reacting antibody to *C. pneumoniae* organisms.

10.2.2. Diagnostic Tests. Chlamydial cultures and serologic techniques are time consuming and expensive; they are not very useful as screening techniques. Amplified DNA technology is extremely sensitive and specific, even on urine specimens and vaginal swabs.[30] As these tests become more available and less expensive they bring the potential of mass screening with non-invasively collected specimens

(first catch urines, self-collected vaginal swabs) will revolutionize control approaches. With the use of these techniques in high-risk young women and men and with single-dose azithromycin therapy now available there is the prospect for detection and elimination of asymptomatic infection, and thus an opportunity for major reservoir reduction, and disease control.

10.2.3. Host Response. Data from individuals with asymptomatic infection have shown that infection may persist in the presence of both serum and local antibody. The contribution of other arms of the immune response to clearance of infection is not clear, but certainly cell-mediated immunity and gamma interferon appear to have important roles in clearing infection.

10.2.4. Control. Control of oculogenital infections due to *C. trachomatis* constitutes a large-scale public health problem. As has been discussed in other sections, true control of these infections will require definition of all the illnesses caused by *C. trachomatis*, and all modes of transmission of infection, coupled with the development of rapid and easily applicable diagnostic techniques.

10.3. Lymphogranuloma Venereum

The outstanding problem in this case, as with the oculogenital syndromes, is the development of a rapid, inexpensive diagnostic method. In this instance, further study of optimal chemotherapy is also needed.

10.4. Psittacosis

In this instance, it would seem that the basic tools are at hand. A vaccine for birds or a more effective antibiotic feed method that would assure elimination of avian infection in less than 30 days would assure better cooperation by the industry.

10.5. *Chlamydia pneumoniae* Infections

There are many research needs for this agent. Culture and serological methods need to be further adapted for this organism. Basic epidemiological and natural history studies are needed. Although serological studies indicate a ubiquitous agent, there appear to be periods of occurrence and absence in given locations. The transmission of the organism, its infectivity, and incubation period need to be defined. Methods of treatment, control, and prevention require extensive research.

It is clear that *C. pneumoniae* can induce a chronic/latent infection. It is not clear whether these persistent infections involve true latency (i.e., persistence of a non-replicating form) or whether this is simply a slower form of replication. It is clear that chlamydial species do a number of things to cells that help them to persist. The chlamydial inclusion avoids fusion with lysosomes, and the infection inhibits host-cell apoptosis, thus allowing the organism when it is in a superficially shorter-lived cell to persist for a longer period of time.

Another important issue is, how do we treat these *C. pneumoniae* infections—particularly when they are chronic infections? If the organism is persisting in a non-replicating stage then those antibiotics which are active against metabolically active bacteria would have no effect. It is not clear that such a chronic persistent infection actually exists; having said that, if this infection does exist, the therapeutic implications are daunting.

Of course, the most important question here is still, does this organism cause coronary artery disease? The failure of treatment trials does not answer that basic question.[89]

CHAPTER 12

Cholera

Manoj P. Menon, Eric D. Mintz, and Robert V. Tauxe

1. Introduction

Cholera is a severe diarrheal illness caused by certain types of *Vibrio cholerae*, that can lead rapidly to dehydration and death. Although other organisms occasionally cause similar illness, the term "cholera" is reserved for illness caused by infection with toxigenic strains of *V. cholerae* O1 or O139, whether the symptoms are mild or severe. Epidemic cholera has appeared relatively recently on the global stage, spreading throughout the world early in the 19th century and causing severe epidemics in the crowded cities of the newly industrializing Europe. Epidemic cholera has since recurred in massive multicontinental pandemics. These pandemics had a profound impact on the development of public health, stimulating the establishment of standing health departments, ongoing infectious disease surveillance, and swift and effective public health response to epidemics. The discovery that cholera was associated with contaminated municipal drinking water spurred the "sanitary revolution," leading to modern water and sewage treatment systems and the control of many diseases in the developed world. Now as then, epidemic cholera continues to goad countries in the early phases of industrialization to develop adequate water and sanitation infrastructures.

Treatment for cholera is simple and highly effective. Rapid replacement of the lost fluids and electrolytes with oral and intravenous solutions can reduce mortality from 25–50% to less than 1%. The organism can be transmitted through contaminated drinking water and through a variety of foods. The specific vehicle of transmission can vary from place to place and during the course of a single epidemic, complicating epidemic control efforts. Efforts to improve drinking water safety and food sanitation can be accelerated by the appearance of epidemic cholera, and prevention can ultimately be achieved by improving the sanitary infrastructure in susceptible areas. Some simple prevention strategies may prove sustainable and effective. Natural infection gives immunity that wanes over time, in the absence of repeated exposure, as do existing and experimental vaccines.

In the 1990s, two events dramatically changed the epidemiology of cholera. The appearance of epidemic cholera in Latin America in 1991, after an absence of over 100 years, stimulated improvements in public health and sanitation throughout the hemisphere. In 1992, a new strain of *V. cholerae*, called O139 Bengal, appeared in India and spread to several countries in south Asia (Figure 1), causing a major epidemic in an adult population that was already largely immune to cholera caused by *V. cholerae* O1 strains. Although the O139 strain has since been relatively quiescent, it may represent the beginning of a new pandemic. The sudden appearance of this serogroup is a case study in the evolution of bacterial serotypes and in the emergence of new pathogens in general.

2. Historical Background

The history of cholera is linked to the early modern era of industrial civilization. Epidemic cholera is not described in early Mediterranean or Middle Eastern medicine texts, though accounts compatible with cholera exist from medieval India.[1] The disease has a homeland in the

Bengal basin, the delta of the Ganges and Brahmaputra Rivers. The vibrio is well-adapted to the estuarine environment and may have been established for many centuries in this natural reservoir, occasionally infecting those who drank or consumed raw shellfish from those waters, in an ecological pattern resembling that of many vibrios, including *V. cholerae* other than O1 or O139.

Beginning in 1817, cholera spread from Bengal to other parts of the world in repeated pandemic waves that affected virtually all of the inhabited world. Precisely when each of these waves began and ended is a matter of historical judgment. The most frequently cited account is that of Pollitzer,[1] who divided them into six major pandemics between 1817 and 1923 (Table 1). The global spread of cholera was hastened by the establishment of European colonies in Asia, which led to increased international trade, and by the steamship, which shortened intercontinental travel times. The Hajj, or annual Muslim pilgrimage to Mecca, helped to disseminate cholera in pandemics four–six.[1] Cholera was likely to have been a regular feature of life in Asia in the 19th century. However, the impact was particularly severe in rapidly growing European cities, where huge lethal epidemics occurred. In those cities, immigrants from the countryside crowded into new slums, seeking employment in the new mills and factories of the industrial revolution. Those Dickensian slums bear a striking sociological resemblance to the barrios, favellas, and periurban slums that ring cities in the developing world today. Investigations of the 1854 epidemic in London by John Snow[2] showed that the cholera death rate in homes served by the Southwark and Vauxhall Water Company was 31 per 1,000 houses, 8.5 times higher than the death rate in homes served by the competing company, which was 3.7 per 1,000 houses. Although neither company provided treated water, the former drew water from

the Thames below the city sewage outlet, while the latter was supplied from the river above the city. An outbreak of cholera was linked to consuming water drawn from one particular and celebrated pump, located in Broad Street. These investigations are classic examples of the application of the epidemiological method even in the absence of a defined microbiological cause. In 1890, similar observations were made in Hamburg, where the incidence of cholera was 34 per 1,000 compared with 3.9 per 1,000 in surrounding areas that were not supplied by water from the River Elbe.(1) These observations catalyzed efforts to provide safe drinking water and adequate sewer systems in Europe and North America.

In 1884, the microbiological cause of cholera was described by Robert Koch(3), who investigated cholera in Egypt during the fifth pandemic. The strains he described are what we now refer to as the "classical" biotype of *V. cholerae* O1, the cause of pandemics five and six.

Epidemic cholera reached the United States on several occasions.(4) In 1832, the nation responded with prayer and panic, and many believed that the disease was a divine retribution afflicting the wicked. Some cities concealed cholera cases, while others ineffectively banned the transit of goods or passengers from suspected cholera-affected areas. By 1866, a more rational approach prevailed. Temporary boards of health were created in many cities, and began to conduct surveillance, to hospitalize cholera patients, and to take measures to improve the municipal water supply. After 1880, in the fifth and sixth pandemics, resurgent European epidemics again threatened the United States. The value of surveillance was widely appreciated, and many local boards of health became permanent institutions. Laboratory diagnosis was used to identify cases. Many municipal aqueducts and protected watersheds date from that era. Large-scale epidemic spread did not occur, suggesting that even then the public health infrastructure was sufficiently advanced to protect the population.(1)

After the sixth pandemic, cholera entered a curious 50-year lull, and again was largely restricted to the Bengal homeland. This lull broke in 1961, when epidemic cholera appeared in Sulawesi, Indonesia, and then disseminated rapidly.(5) This seventh pandemic was caused by the El Tor biotype of *V. cholerae* O1. It spread rapidly across Asia and into Africa by 1970 (Figure 2).

Events in the 1990s changed the epidemiology of cholera. In 1991, after a greater than 100-year absence

Figure 3. Countries/areas reporting cholera cases in 2007, World Health Organization.[8]

of epidemic cholera, a variant E1 Tor strain appeared in Peru in a new epidemic wave that spread swiftly through Latin America. By November 1991, cholera was reported in 12 Latin American countries, affecting over 330,000 individuals.[6] Additional cases were subsequently reported from other Latin American countries during this epidemic and accounted for over 65% of all reported cases globally in 1991.[7] More recently, perhaps due to improvements in public health and sanitation, the reported cases of cholera have dramatically decreased in that region.[7]In 1992, a new serogroup of *V. cholerae*, called O139 Bengal, appeared in India and caused a major epidemic in a population that was already largely immune to cholera caused by *V. cholerae* O1 strains. *Vibrio cholerae* O139 possesses epidemic potential but after a brief excursion into South East Asia, it has been largely restricted to south Asia for unknown reasons. In the mid-1990s, following the dissolution of the Soviet Union, epidemic cholera appeared in the decaying cities of central Asia, revealing the importance of a sound public health infrastructure. Epidemic cholera continues to exert a major influence on the global development of society and public health, disproportionately targeting impoverished areas lacking in improved public health and sanitation systems. The World Health Organization (WHO) continues to receive reports of cholera from most regions of the world; data from central Asia, central America, and Latin America were not available in 2007 (Figure 3). In 2007, the WHO confirmed more than 177,963 cases (Figure 4) and 4031 deaths from cholera. These numbers include 45 confirmed cholera epidemics, 83% of which occurred in Africa.[8]

3. Methodology

3.1. Sources of Mortality Data

Cholera was the first disease for which modern public health surveillance was organized. Thus, cholera bears the code 001 in the international classification of diseases and, along with plague and yellow fever, cholera is an internationally notifiable disease. The cholera epidemics of

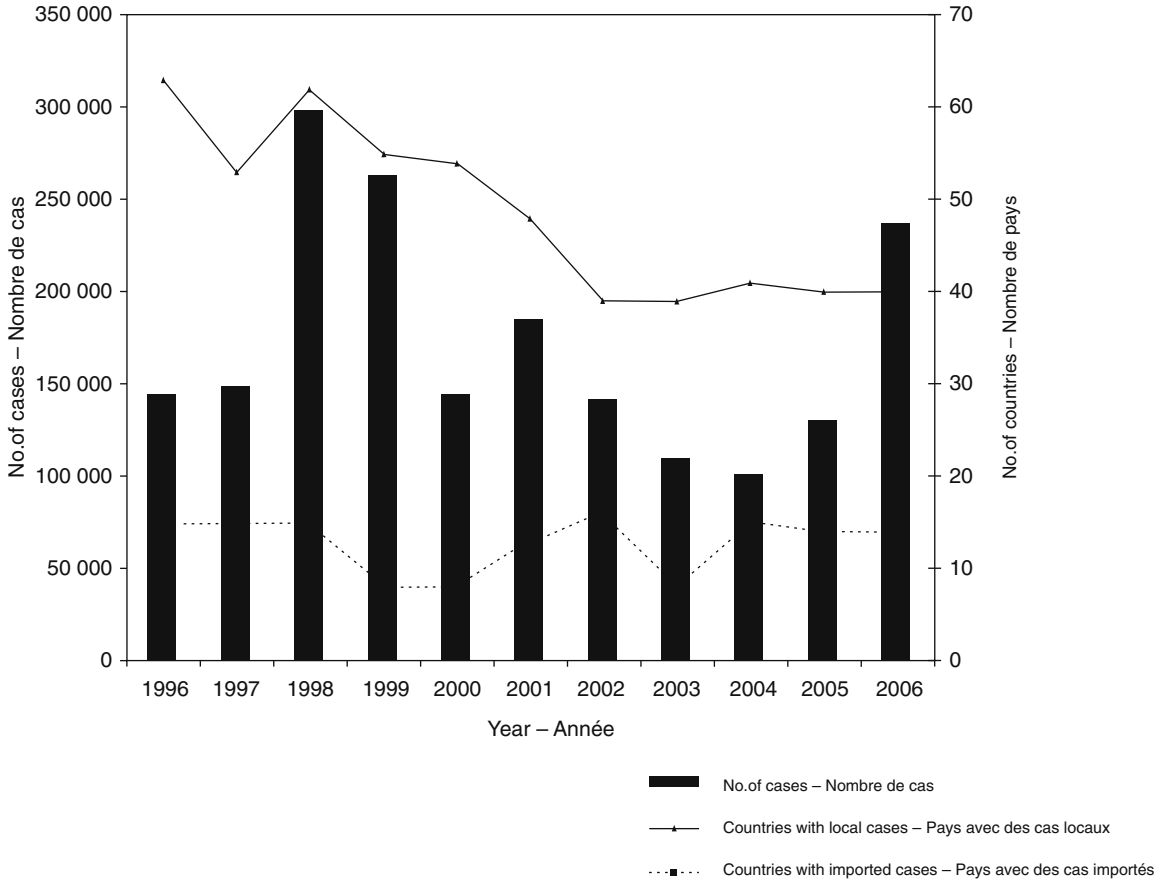

Figure 4. Countries/areas reporting cholera and cases reported to World Health Organization by year, 1997–2007.[8]

the 19th century prompted the development of the current International Health Regulations (IHR). The IHR have recently been revised to include the notification of diseases which constitute a "public health emergency of international concern". [9] Cholera continues to meet this definition. These regulations, which were adopted in 2005, were implemented beginning in 2007. Many countries conduct routine surveillance for cholera and report the results to the World Health Organization (WHO). Political concerns, fear of inappropriate trade embargoes or loss of tourism, and other imagined penalties cause some countries to conceal the presence of cholera. In particular, Egypt, Thailand, and Bangladesh have for years officially denied the presence of cholera, referring instead to "severe diarrheal illness." In many other countries, particularly in Africa, vital statistics are not routinely gathered, disease reporting is limited, and many cases and deaths go unreported. Thus, official global statistics on cholera provide a very incomplete picture.

The definition of a cholera death varies greatly. The definition recommended by the Pan-American Health Organization is "death within 1 week of onset of diarrhea in a person with confirmed or clinically defined cholera."[10]

3.2. Sources of Morbidity Data

Although cholera is a notifiable disease in most countries, the actual number of cases reported is far less than the number that occur. In parts of South Asia, infection with *V. cholerae* is probably nearly universal, yet no cases are reported. The definition of a case used for surveillance purposes varies considerably.[10] The WHO definition categorizes cases as suspect or confirmed and is dependent on whether cholera is endemic to the region. A suspect case of cholera in a non-endemic region occurs when "a patient, 5 years of age or older, develops severe dehydration or dies

from acute watery diarrhea". [11] In an endemic region, a patient older than 5 who "develops acute watery diarrhea, with or without vomiting" meets the suspect case definition. A confirmed case is dependent on isolation of either *V. cholerae* O1 or O139. Regardless of laboratory confirmation, all cases of cholera are included in WHO surveillance data. The precision of the surveillance definition is improved by excluding those persons under the age of 5 years, given the numerous other causes of pediatric diarrhea, at the expense of counting younger patients. [12] In Peru, the positive predictive value of this simple case definition was better than 80% early in the epidemic.[13]

When cholera is rare, other severe diarrheal illnesses will be more common than cholera, which renders the clinical definition too nonspecific for public health use. Therefore, in most industrialized nations, the surveillance case definition of cholera depends on laboratory isolation of toxigenic *V. cholerae* O1 or O139, or demonstration of diagnostic antibodies.[14] Because many other *V. cholerae* cause occasional illnesses, without the same public health implications, it is important in the setting of a sporadic infection to verify the serogroup of *V. cholerae* as O1 or O139 and the toxigenicity of the organism before calling the illness cholera.

Where cholera is common, case reporting and public health response should not be limited to laboratory-confirmed cases. It is not necessary to expend scarce laboratory resources confirming many thousands of cases during an epidemic; the most useful roles of the laboratory are to initially identify the organism causing the epidemic, to monitor changes in antimicrobial resistance during the epidemic, and to establish that an epidemic is over.[15]Additionally, laboratories play an integral role in identifying the source of infection and extent of the epidemic. As such, microbiologists, in addition to epidemiologists, should be included in epidemic response and control teams.

3.3. Surveys

For many years, the International Center for Diarrheal Disease Research in Bangladesh has maintained surveillance of urban and rural populations, defining the epidemiology of cholera in that area. Population-based surveillance has also been conducted in Kisumu, Kenya. [16]

Serological surveys conducted in the epidemic setting show that the actual number of infections will exceed the reported clinical cases by at least 10-fold.[17] The seroepidemiology of cholera depends on the specific but short-lasting vibriocidal antibody response, so long-term retrospective serosurveys like those done for viral pathogens cannot often be meaningfully conducted for cholera.

In the developed world, when a cholera case is detected, it may be useful to heighten local surveillance to detect other cases, and thereby establish whether transmission is ongoing. This is done by obtaining cultures from patients with severe diarrhea coming to medical attention and by testing convalescent sera from severe diarrheal cases seen at medical facilities in the preceding weeks.[15,18] If sewage collection is centralized, culturing gauze Moore swabs placed in the main sewer for 24 h can detect *V. cholerae* in areas drained by the sewer.[19] This is an economical way of maintaining surveillance on a population among whom cholera might be introduced.[15]

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of the Organism. *Vibrio cholerae* is excreted in stools of the cholera patient and grows well on several standard bacteriologic media. Efficient isolation depends on the use of a selective medium that suppresses other bacterial species, while permitting *V. cholerae* to grow. Thiosulfate–citrate–bile salts–sucrose (TCBS) agar is the most widely used medium.[15] Alkaline peptone water (APW) is frequently used as an enrichment broth. [15]*Vibrio cholerae* produces large yellow colonies on this medium. The isolates are further characterized biochemically and tested with diagnostic antiserum for the presence of O1 antigen. The O1 strains will agglutinate in the O1 antiserum, producing a coagulated clump on a slide. In the same manner, O139 strains can be identified with O139 antiserum. Strains that agglutinate in neither O1 nor O139 antiserum may be non-O1, non-O139 strains of *V. cholerae* or other closely related vibrios (such as *Vibrio mimicus*). Definitive identification of such strains may require the services of a reference laboratory, but is not necessary if the only concern is cholera. Strains that agglutinate in O1 antiserum can be further characterized as serotype Inaba or Ogawa by using monovalent antisera.

For environmental or food specimens, in which the number of *V. cholerae* organisms may be much lower than in stools, an enrichment step is often necessary. Incubating the specimen in APW for 8 h takes advantage of the affinity *V. cholerae* has for alkaline environments; the broth is subsequently plated on TCBS.[15]

The O1 or O139 strains should be further characterized by whether or not they produce cholera toxin. This was originally measured by the ability of supernatant from a broth culture to induce the outpouring of fluid in the rabbit ileal loop, but is now detected by tissue culture assay, latex bead agglutination, enzyme-linked immunosorbent assay,[15]or PCR. [20]

Strains can be further characterized by biotype, of which there are two, classical and El Tor. However, because

classical biotype is restricted to coastal Bangladesh, the need for biotyping is minimal in most places.

Within biotype E1 Tor, subtypes can be defined by using traditional and molecular techniques (see Section 4). Subtyping is of value in epidemiological investigations to help determine the source of infecting strains.

Some more rapid presumptive diagnostic methods exist. The characteristic darting "shooting star" motility of vibrios can be observed by microscopy of a wet mount of fresh feces and halts immediately if O1 antiserum is added to the slide.[21] A commercially available diagnostic test based on colorimetric immunoassay detection of O1 antigen offers rapid presumptive diagnosis in the field without microscopy.[22,23] The efficiency of this test equals that of traditional microbiological methods; using the test provides greater speed of diagnosis at higher cost. A recent evaluation of this test and two other rapid diagnostic methods revealed that a dipstick assay using monoclonal antibodies in the detection of *V. cholerae* O1 and O139 lipopolysaccharides was highly sensitive in the hands of both field workers and laboratory technicians.[24] This feature, along with the fact that it does not require refrigeration, makes it a potentially useful tool in outbreak detection. It has recently been made available through the commercial sector at a cost of roughly US $1.

Rapid methods do not yield a living organism for confirmatory or antimicrobial resistance testing. Since a patient with severe diarrhea requires rehydration therapy whether or not cholera is confirmed, rapid tests should not affect management of the individual patient. Rapid diagnosis may prove most useful when it is linked to public health actions that slow the spread of an epidemic.

3.4.2. Serological and Immunologic Diagnostic Methods. The human immune response to infection with toxigenic *V. cholerae* O1 has been well characterized.[25] Within 10 days, vibriocidal antibodies appear in the serum, which, like viral neutralizing antibody, rapidly kill target *V. cholerae* O1. This response begins to decline by 1 month and then disappears after a year. There is no difference between antibodies evoked by Ogawa or Inaba strains, though in general, classical strains appear to evoke higher antibody responses than E1 Tor strains. The somewhat slower antitoxic response peaks by 21–28 days after exposure and remains elevated for several years.

Serodiagnosis of the single case depends on demonstration of a fourfold rise in vibriocidal titers between early and convalescent sera or a fourfold fall between convalescent and late convalescent sera.[15] Detecting antitoxin is suggestive evidence and is helpful when trying to distinguish between vaccine-induced and natural immunity (if the vaccine does not contain toxin subunits). However, similar antibodies appear after infection with *Escherichia coli* producing heat labile enterotoxin (ETEC LT). Methods for distinguishing the two responses exist and are applicable in population surveys, but they may not resolve the isolated case.[26]

The immune response to infection with toxigenic *V. cholerae* O139 is incompletely understood.[27] However, it appears that previous infection with O1 does not offer protection against O139.[28,29] A study comparing the immune response of patients infected with these two serogroups revealed that both serogroups can elicit a vibriocidal and cholera toxin-specific response. Similar to the response seen with toxigenic O1, patients infected with O139 had a cholera toxin-specific response and LPS-specific antibody response which peaked by day 7.[29]

4. Biological Characteristics of the Organism

Vibrio cholerae organisms are gram-negative, comma-shaped rods, adapted to life in brackish water. They are highly motile, with a long terminal flagellum that propels them through water, and they metabolize a wide variety of nutrients. They grow most rapidly at a pH that is neutral to somewhat basic, in moist environments with traces of salt and organic matter. This includes many foods, such as cooked grains, like rice or lentils, and cooked shellfish.[30] They are exquisitely susceptible to drying, sunlight, and acid, and die rapidly at pH of 4.0 or less. Humans are the only vertebrate host.

Serogroups of *V. cholerae* have been defined on the basis of their surface antigens. Like other gram-negative organisms, *V. cholerae* produce lipopolysaccharide O-antigen with a variety of terminal sugar groups that can be differentiated serologically. The flagellar antigens (H-antigens) do not vary within the serogroup and are not used for subtyping.[31] Only two serogroups, O1 and O139 are "choleragenic" and hence have the ability to cause epidemics. Both of these serogroups possess the cholera toxin, an important virulence determinant for *V. cholerae*. Within the O1 or O139 serogroups, nontoxigenic strains occasionally occur that may cause diarrhea but do not cause cholera. Cholera toxin is a protein enterotoxin formed from an active A subunit of 240 amino acids, held within a pentamer ring of five B-subunits, each of which has 103 amino acids.[32] The organism varies the amount of toxin produced depending on its immediate environment.[33]

Within the O1 serogroup, two specific antigenic serotypes, called Ogawa and Inaba, have been defined. Serotype switching has been observed within a given strain, so that these are not stable markers.[13]

Toxigenic O1 strains can be separated into two biotypes: El Tor and classical. El Tor strains agglutinate chicken red cells and lyse sheep red cells, while classical strains do neither; the two biotypes can be separated by phage

susceptibility studies as well.[34] Classical strains caused global pandemics in the late 19th and early 20th centuries, but since then have been restricted to rural Bangladesh.[35] The El Tor biotype of *V. cholerae* O1 is named for a Hajj quarantine station in Egypt, where it was isolated from an asymptomatic pilgrim early in the 20th century. Its epidemic potential was debated until the beginning of the seventh pandemic in 1961. There are important epidemiological differences between the two biotypes. Compared to classical strains, El Tor strains are more likely to produce inapparent infections,[17] persist longer in the environment,[36] multiply more rapidly following inoculation into foods,[30] and evoke less complete immunity.[37]

Toxigenic *V. cholerae* O1 El Tor strains can persist in rivers and estuaries for long periods, indicating they have niches in nature that are independent of human fecal contamination. This persistence is best demonstrated for the unique strain found along the US Gulf Coast[38] and for that found in the saline rivers of northeastern Australia,[39] though other natural foci are likely to exist. The precise nature of the niche is unknown, though several clues point to an association with plankton. *Vibrio cholerae* O1 produces chitinase, an enzyme that dissolves chitin, the structural protein of invertebrate exoskeletons.[40] This suggests they may have a niche in the digestive tracts of marine life that eat crustacea, or even a role in the growth and molting pattern of some crustacea. They can attach directly to crustacea, particularly to zooplanktonic copepods, without harming them.[41] They may persist in association with certain algae.[42] A dormant phase, the so-called "viable but noncultivable state," has been hypothesized to describe the persistence of *V. cholerae* in the environment between epidemics.[43,44]Environmental factors, including temperature and salinity, may allow for the transition between the dormant and transmissible phase.[45]

Three other enterotoxins produced by *V. cholerae* O1 have been described although their role in human disease is uncertain. These are zona occludens toxin (ZOT),[46] accessory cholera enterotoxin (ACE),[47]and WO7 toxin.[48]It appears that the ACE results in the secretion of Cl^- and HCO_3^-, mediated by Ca^{2+} as a second messenger.[49] The ZOT induces a diarrheal response by reversibly altering the structure of the tight junctions, and hence increasing mucosal permeability.[50]Although the mechanism of the WO7 toxin is uncertain, it does agglutinate rabbit erythrocytes and produce fluid accumulation in the rabbit ileum.[48]

In addition to cholera toxin, a pilus colonization factor, toxin coregulated pilus (TCP), is necessary to cause disease.[51] While cholera toxin is encoded by a lysogenic filamentous bacteriophage, CTX,[52] the mechanism of TCP acquisition is still uncertain.

Vibrio cholerae O139, first detected during outbreaks of cholera-like illness in 1992 in India,[53] appears to derive from O1 strains of biotype El Tor. Although it shares biological traits, including the production of cholera toxin, with *V. cholerae* O1, *V. cholerae* O139 does not agglutinate with O1 antisera[53], and possesses both a capsule and a distinct lipopolysaccharide.[54] A portion of the genome coding for O-antigen synthesis has been deleted from otherwise typical El Tor O1 strains, and genes have been inserted that code for a different antigen expressed as a polysaccharide capsule.[55]This evolutionary event appears to be mediated by horizontal gene transfer via a bacteriophage.[56] The noted differences between O1 and O139 may explain the lack of cross-protection.

Molecular subtyping methods have revealed a surprising diversity of subtypes within epidemic strains. Even the highly conservative methods of multienzyme electrophoresis identify four main enzyme types (ET) within El Tor strains, representing the Gulf Coast, Australian, seventh pandemic, and Latin American strains; the same method showed that at least three subgroups could be distinguished in the classical biotype.[57] Ribotyping identified nine ribotypes (RT) among 176 toxigenic El Tor strains tested.[58] With pulsed field gel electrophoresis (PFGE), 36 patterns were identified among 142 toxigenic El Tor strains tested, offering a fine-grain subtyping that is useful for epidemiological investigations.[59] The Latin American epidemic strain, introduced in Peru in 1991, remained relatively uniform,[60] although some minor genetic variations emerged in strains from Lima during the first few years of the epidemic.[61] The diversity of epidemic strains in Latin America increased as the original one was joined by other strains, likely to represent separate introductions.[60,62,63]

These findings are consistent with the seventh pandemic in the rest of the world, which is caused by an overlapping patchwork of strains. Using the same methods, strains associated with the O139 epidemic can be divided into at least two ribotypes and four PGFE types from the beginning, indicating that the epidemic of O139 infections is caused by more than one "epidemic strain."[64]

The genes coding for cholera toxin B-subunit also show diversity, and at least three subtypes exist.[65] All toxin types appear to have the same biological activity. Curiously, the Gulf Coast El Tor strains have the same B-subunit type as otherwise unrelated classical strains, suggesting that toxin genes have transferred horizontally between unrelated bacteria.

Vibrio cholerae of other non-O1 serogroups can sometimes cause human illness, including diarrheal illness and lethal invasive infections, but have not spread in epidemic form. Although they are often isolated from the aquatic

environment, most non-O1 *V. cholerae* serogroups are of little importance to public health, and care is needed in the interpretation of reports that do not specify the serogroup under discussion. Recently, isolates of *V. cholerae* O141 that possess cholera toxin and are capable of causing severe cholera-like illness have been described in sporadic cases in the United States and elsewhere.[66, 67] To date, no outbreaks or epidemics have been attributed to this strain.

The complete genome of *V. cholerae*has been recently sequenced. It consists of two circular chromosomes, the larger chromosome I, comprising some 2.96 million bp, contains most of the essential genes as well as loci determining virulence.[68] The toxin-associated genes reside within a lysogenized filamentous phage, consistent with the hypothesis that they originated from another organism via horizontal transfer.[52] Chromosome II, which consists of roughly 1.07 Mb, may have been acquired as a plasmid or by excision from a single large genome and harbors unique copies of critical genes, including a large cluster of integrons, mobile DNA elements capable of gene acquisition.[68]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

In 2007, 53 countries reported cholera to the World Health Organization.[8] The 117, 963 cases and 4,031 deaths reported in 2007 are only a small fraction of the true global total and are largely driven by Africa, which reported 116, 583 cases, 94% of the total, including large outbreaks in multiple countries. A recent review of WHO data on reported cholera cases and deaths revealed that the incidence of indigenous cholera in sub-Saharan Africa was 95 times higher than the reported incidence in Asia and 16,600 times higher than the reported incidence in Latin America in 2005.[69] Over 60% of all cases reported globally were reported from just four countries in Africa (Angola, Democratic Republic of Congo, Ethiopia, and Somalia). In 2007, the reported case fatality rate in Africa was 2.4%—seven times greater than the rate reported in Asia (0.33%).[8] These differences may reflect differences in reporting (for example, no deaths were reported from Bangladesh), pre-existing immunity, host factors (such as blood group—see Section 5.7), and the delivery of medical care to cholera patients. There is no evidence to suggest a change in the virulence of the organism.

The incidence of cholera depends on the presence of the causative organism, the opportunities available for its transmission, and the population immunity. Where sanitation is poor and crowded and previously uninfected populations are at risk, cholera incidence can be extremely high. However, even then most infections are asymptomatic. It has been estimated that 2% of infections are severe, 5% are moderate, and 18% have mild symptoms; up to 75% of infections are inapparent.[17] In the first year of the epidemic in Peru, 1.5% of the population was reported to have clinical cholera,[70] and by early 1995, this had risen to 3%.[71] It is likely that most Peruvians were infected. In remote African villages affected by outbreaks, incidence was 1.5 per 100.[72] In Bangladesh, where infection is likely to be nearly universal and repeated, silent infections maintain a relatively high level of immunity in the population. Nonetheless, the annual incidence of cholera requiring hospitalization ranges from 0.2 to 5 per 100.[73]

Different strains of *V. cholerae* may compete with each other. In Bangladesh, where E1 Tor and classical biotypes of *V. cholerae* coexist, the relative prevalence of these strains varies from year to year unpredictably, possibly reflecting shifts in the underlying ecology.[35,73] In 1992, *V. cholerae* O139 emerged in Bangladesh, caused epidemic disease, and transiently displaced O1 as the dominant strain.[74] While O139 continued to dominate in the southern coast region of Bangladesh, by 1994, a new clone of O1 was again seen in the northern and central areas.[75] Between 1996 and 2002, cholera was primarily attributed to O1. In early 2002, O139 again emerged as the epidemic strain.[76] Surveillance studies indicate that multiple ribotypes of O139 are now present. If genetic changes provide an evolutionary advantage, more widespread dissemination of the O139 strain may yet occur.[76]

5.2. Epidemic Behavior and Contagiousness

Cholera can appear as a single isolated case, as focal outbreaks, or in large epidemics. In the developed world, even sporadic cases are rare and are usually the result of travel to the developing world or of consumption of undercooked shellfish harvested from a natural reservoir, as with other *Vibrio* infections. When focal outbreaks occur, they are due to a common food source, and secondary transmission is rare.

In the developing world, where sustained transmission is possible, a single case or a focal outbreak can lead to larger epidemics. In small closed groups, such as a village or barracks, transmission halts after several weeks, when there are no more susceptible individuals or when effective control measures are introduced. In larger populations, an epidemic can persist for many months, slowing in the cooler season and then recurring the following year. In some areas, cholera then disappears; in others, it recurs regularly for many years, presumably because the organism finds an environmental niche. A long-term carrier state has been described

in humans, but is extremely rare and does not play a defined role in the persistence of the organism.[77]

Throughout the 19th and early 20th centuries, cholera rarely lasted more than a few years in one location. However, since the beginning of the seventh pandemic, cholera has tended to persist or recur once it was introduced. Cholera remains a public health threat in Africa now, nearly four decades after it entered that continent in 1970. Indeed, nearly 94% of the reported cases of cholera in 2007 were from Africa, a percentage consistent over the past decade.[8] While it persisted for some years in several areas of Latin America since its arrival 1991, this region did not report any cases of cholera in 2007.[8] This tendency to persist may be related to the specific properties of E1 Tor strains. It may also be related to the far greater density and mobility of human populations now compared with 100 years ago. It suggests that in the absence of major improvements in water and food quality and sanitation, or widespread implementation of effective immunization campaigns, cholera will remain an important global public health threat for many years to come.

Because a large inoculum is required to produce disease, cholera is rarely transmitted directly from one person to another without the intervening contamination of food or water. Caregivers themselves are very unlikely to become infected. Episodes of nosocomial transmission are likely to be the result of contaminated water or infant formula, not direct person-to-person spread.[78] Cholera often spreads within households in the developing world. On the Micronesian island of Chuuk (Truk), this was particularly likely if the first case in the household occurred in the food preparer.[79] In Kolkata, secondary cases were more likely if the household stored drinking water in a large-mouthed container, where it was easily contaminated.[80] Cholera outbreaks have occurred among persons attending funerals of cholera victims. This is less likely to be due to simple contact with the cadaver, and more likely to be due to consuming foods and beverages at a funeral meal that were prepared by bereaved family members after they prepared the corpse for burial.[81]A case–control study to assess the role of disinfection and funeral activities was conducted during a 1994 outbreak in Guinea-Bissau. This study revealed the protective effect of disinfection, finding an association between disease and eating at a funeral with a non-disinfected corpse as well as touching a non-disinfected corpse.[82]

When an epidemic occurs, it is sometimes possible to determine the original source of the infection. This may be a traveler who arrives while still incubating the infection, someone bringing contaminated foodstuffs with them, or even the body of a victim being brought back to an ancestral village for burial. It is rare to identify any measure that could have prevented the introduction. *Vibrio cholerae* can also be introduced via ocean freighters, which take on ballast water in one harbor and discharge it in the next, contaminating shellfish beds near harbors in the process.[83] To decrease this risk, freighters are now required by the International Maritime Organization to exchange their ballast water while at sea. The source of the unique strain that appeared in Latin America in 1991 remains unknown.[70] Several theories regarding its source have been postulated, including freighters with passengers from cholera endemic areas,[70] dissemination by cargo ship ballast,[84] and phage-mediated virulence gene transfer.[85] There has also been speculation that environmental changes associated with the El Nino phenomenon in 1991 could have fueled increased concentration of vibrios in the coastal waters.[86] Throughout the world, the tides of humanity that flow from place to place can introduce cholera as long as it persists anywhere.

5.3. Geographic Distribution

The seventh cholera pandemic has affected most of the developing world (Figure 2). Developing countries with higher levels of sanitation, such as Chile, Argentina, and Costa Rica, tended to have relatively low attack rates, and even in countries affected by epidemics, areas with better sanitation were less likely to be affected. In Mexico, cholera displayed a north–south incidence gradient, with the highest incidence in the poorest southern states.[70]

Unique strains of *V. cholerae* O1, biotype E1 Tor, persist in environmental reservoirs along the US Gulf Coast and in rivers of northeastern Australia. Strains of *V. cholerae* O1, classical biotype, are now limited to coastal Bangladesh, while E1 Tor biotype strains are found farther inland in the same country, suggesting that the two differ in their ecological requirements.[35]

Spread of the epidemic strain, *V. cholerae* O139 Bengal, has so far remained restricted to Asia (Figure 1), but could in the future reach Africa and other parts of the developing world, potentially causing the eighth pandemic.

5.4. Temporal Distribution

Cholera is sharply seasonal, becoming rare or undetectable in cooler months. It is not known what determines this seasonality or how the organism survives from one season to the next, however, recent data suggest that cholera phages may be responsible. The presence of phages were shown to be inversely related to the presence of *V. cholerae* strains found in the environment and to the number of reported cases.[87] Further, the ability of vibrios to become dormant, in the viable but non-culturable phase, in response to environmental factors may allow for their persistence. In the Latin American epidemic, cholera

increased sharply in the early summer and declined slowly in the fall. The calendar month affected varies with the hemisphere, peaking in July through September in the Northern Hemisphere and from January through March in the Southern Hemisphere.[70] Along the US Gulf Coast, the same seasonal pattern prevails.[88] In Asia, the seasonality tends to be predictable in a given location, but it is not uniform across the continent. Attempts to relate seasonality to rain, monsoon, or water temperature are inconsistent. In the 1950s, the peak season for cholera in Kolkata was May and June, just before the monsoons, while in Chennai, farther south on the same coast of India, it was August and September at the end of the monsoons.[1] In rural Bangladesh, the seasonality of E1 Tor and classical infections differ: the peak for E1 Tor is October–November, and for classical biotype is in December–January.[73] The seasonality may be related to the presence of algal blooms.[89] Whether this association is related to the environmental factors which favor algal bloom growth or their disintegration is unknown. One hypothesis suggests that the nutrients released at the end of algal blooms may favorably affect the growth of *V. cholerae*.[90]

Year-to-year variation in incidence can be substantial and may also reflect shifts in underlying ecology (Figure 4). In British Colonial India, it was noted that the year following a year of drought had a higher incidence of cholera.[91] Along the Gulf Coast, the years with highest incidence also happened to be years of drought, when saltwater incursions moved further inland than usual. No general predictive rule is known.

5.5. Age

When cholera affects a population that has no preexisting immunity, the age distribution of cholera patients reflects exposure to infection. In Piura, Peru, where the town water and street-vended beverages made with ices were identified sources, nearly all ages were equally exposed. Incidence in the first 3 weeks of the 1991 epidemic was 1.3% among those aged 5–14 years and 1.8% among those over 15 years of age.[92] In Italian outbreaks of 1973, transmission occurred through contaminated raw shellfish that were usually eaten by adults, so the median age of patients was 52 years.[93] Because gastric acidity declines with advancing age, the elderly are often more likely to have severe illness than younger persons. In Mexico, in 1991, the incidence among those over age 65 years was 7.1 per 100,000, compared with 2.5 among persons aged 15–24 years.[70]

In Bangladesh, where many adults have natural immunity that may be boosted by repeated exposure, cholera caused by *V. cholerae* O1 is more typically an illness of children, though cases in adults are not rare.[73] Breastfeeding infants are protected because they are not exposed to contaminated water and food and also because of passive protection of antibodies in maternal milk.[94] When epidemic *V. cholerae* O139 infections appeared in the Bengal area, pre-existing immunity to O1 strains had little effect, and all ages were affected.[95]

5.6. Sex

The gender of the patient does not affect the outcome of infection or the rate of infection, given equal exposure.

5.7. Race

Cholera and race are not specifically linked. However, severe manifestations of cholera are strongly associated with blood group O, the frequency of which varies among races. Persons of blood group O are more likely to have severe cholera than persons of other blood groups. In Bangladesh, where blood group O is relatively uncommon, most adults hospitalized with cholera were of blood group O.[96] It has been speculated that the reason that blood group O is so rare in this population is that cholera itself provided a selective pressure over many centuries. In the Americas, most native peoples are blood group O, so this blood group is extremely common throughout Latin America. In Peru, persons with blood group O were no more likely to be infected with *V. cholerae* than others, but if infected they were ninefold more likely to develop life-threatening diarrhea than persons with other blood groups.[97] The reason for this strong association is unknown.

5.8. Occupation

Few occupational associations are apparent in cholera epidemics or outbreaks. Fishermen and harbor workers may be the first to be affected. The first case of cholera on the US Gulf Coast occurred in a shrimp fisherman in 1973.[98]

Notably absent are cases among health staff caring for cholera patients, among microbiologists, and among undertakers preparing the bodies of cholera victims for burial. The extreme rarity of such cases underscores the ease with which simple hygienic precautions prevent cholera transmission.

5.9. Occurrence in Different Settings

Cholera epidemics occur when breaks in sanitation lead to contamination of water and food consumed by many people. The most characteristic setting is the large periurban slum, where people newly arrived from rural areas outstrip the availability of basic urban services (see Section 6). Temporary gatherings have also been recurrent sites of cholera outbreaks, including religious pilgrimages and

refugee encampments. Historically, the Islamic Hajj has played an important role in disseminating pandemics, as have the great religious migrations of India.[1] Cholera has not complicated the Hajj in recent years, perhaps because of efforts to provide better sanitation during the pilgrimage; pilgrimages in Bangladesh may have accelerated the spread of *V. cholerae* O139. Concern for the spread of cholera at traditional Andean pilgrimage sites, such as Copacabana on Lake Titicaca, prompted authorities to limit the size of the pilgrim population and to match it with latrine and potable water facilities; to date, pilgrimages have not been a major source of spread of cholera in Latin America.

Refugee camps in Asia and Africa have experienced large epidemics of cholera. These epidemics are most severe when the camps are just being established or are overwhelmed with a new influx of people. The sudden migration of 700,000 Rwandan refugees to bare lava fields near Goma, Zaire in the summer of 1994, where there were no latrines or wells, led to a catastrophic cholera and dysentery epidemic that killed 5% of the population in the first 3 weeks of the camp.[99] Cholera had recurred in the region for years, suggesting there is an environmental reservoir in Lake Kivu, the water of which was drunk without chlorination. In more organized camps of Mozambican refugees in Malawi, epidemic cholera was recurrent, though with better medical care the mortality was lower. Cases disproportionately affected children and were most common among the most recent arrivals to the camps, who lacked cooking gear, fuel, and water storage pots as well as those who drank river water.[100] However, cholera is not inevitable among refugees.[101] Cholera outbreaks were rare among Vietnamese refugees in Thailand and were easily controlled once the source was determined.[102]

Epidemic cholera has rarely followed natural disasters, except in the Bengal basin. In Bangladesh, epidemics of "severe diarrheal disease" occur after typhoons flood coastal regions, in areas that would have had many cholera cases even without unusual flooding. In 1998, a large epidemic, with greater than 16,500 reported cases and 276 deaths, occurred after severe floods in West Bengal, an area with endemic disease.[103] On December 26, 2004, a devastating tsunami, which originated in the Indian Ocean, killed an estimated 275,000 people in affected countries around that ocean. Although this event raised concern for the spread of a host of infectious diseases, there has been no confirmed cholera cases reported to WHO related to this tragedy.[104]. Similarly, although sporadic cases of wound and gastrointestinal *Vibrio*infections were reported following Hurricane Katrina's devastation of the US Gulf Coast, epidemic cholera did not occur.[105]Surveillance did identify two cases of toxigenic *V. cholerae* O1 reported in New Orleans in the weeks after Hurricane Katrina.[106] Both cases were associated with consumption of inadequately cooked Gulf Coast shellfish.

5.10. Socioeconomic Factors

In most epidemics, cholera is associated with extreme poverty. In the developing world today, just as in the industrializing cities of Europe over 150 years ago, better housing usually implies better water and safer food supplies. Behaviors that protect against cholera cost money: these include boiling water, storing it in special containers to protect it from recontamination, and heating food for each meal rather than eating cold leftovers.

5.11. Other Factors

Because vibrios are exquisitely sensitive to acid, the patient's gastric acid barrier is important. Gastric acid production is decreased by gastric surgery for ulcer disease, by antacid or antiulcer medication, and in the youngest infants and those of advanced age. This risk factor can be an important determinant of who gets ill. For example, in an Italian outbreak in 1973, 27% of patients had had gastric surgery.[93] The impact of infection with the gastric bacterium *Helicobacter pylori*, which can induce a state of hypochlorhydria, is less well understood but may be important (see Chapter 18). A cross-sectional study of the 1991 epidemic in Peru found that *V. cholerae* O1 was associated with infection with *H. pylori*. This association was more pronounced in children and yielded a greater adjusted odds ratio than blood group O.[107]

6. Mechanism and Routes of Transmission

Cholera follows ingestion of food or water contaminated with an infectious dose of the causative organisms. In epidemics, the source of contamination is usually the feces of infected humans. In sporadic cases associated with natural reservoirs, no fecal contamination need occur.

In the United States, the majority of cases are acquired outside of the country.[108] Locally acquired cholera is usually associated with eating undercooked seafood harvested on the Gulf Coast.[98] One outbreak on a Texas oil platform in the Gulf of Mexico followed contamination of rice with seawater, which itself was contaminated by the platform's sewage line; it is presumed that fecal contamination played a role.[109] Other cases have been related to foods that have been cross-contaminated[108] documented by one outbreak

Table 2. Precautions for Travelers to Areas with Epidemic Cholera[a]

- Drink only water you have boiled or treated with chlorine or iodine. Other safe beverages include tea and coffee made from boiled water and carbonated, bottled beverages with no ice
- Eat only foods that have been thoroughly cooked and are still hot, or fruit that you have peeled yourself
- Avoid undercooked or raw fish or shellfish, including ceviche
- Make sure all vegetables are cooked—avoid salads
- Avoid foods and beverages from street vendors
- Do not bring perishable seafood back to the United States
- A simple rule of thumb is "Boil it, cook it, peel it, or forget it"

[a]From CDC public information brochure, "Cholera Prevention," published May 1992. Available at the Web site http://www.cdc.gov/ncidod/dbmd/diseaseinfo/cholera_g.htm

which followed the contamination of a melon by an asymptomatic food preparer.(110) Additional cases are brought from countries where cholera epidemics were occurring, e.g., two outbreaks were traced to crabs from Ecuador and an outbreak was related to fresh frozen coconut milk imported from Thailand.(98, 111)

Travel-associated cases typically occur among persons who are visiting friends or relatives in their own countries of origin in the developing world. These travelers tend to be exposed to the same risks of cholera as the developing country population. Cases among more typical tourists or business travelers are extremely rare. The overall infection rate is remarkably low, approximately 1 per million air travelers to affected countries.(88) Simple precautions should prevent most of these cases (Table 2).

In the developing world, transmission of cholera has been documented through a variety of water and foodborne mechanisms. During epidemics, infections can be spread by more than one mechanism, and the dominant source of infection may change. In an epidemic on the Gilbert Islands, the initial cases were caused by consumption of partially dried salted fish, but a month later illness was associated with eating a variety of raw clams and shrimp as well as salted fish.(112) In 1974, during a cholera epidemic in Portugal, an initial wave of cases associated with eating raw shellfish was followed by a sudden surge when a popular brand of bottled water became contaminated, thereby infecting those who drank the water precisely to avoid cholera.(113,114) In eight collaborative investigations into the mechanisms of transmission of cholera in Latin America, multiple mechanisms of transmission were identified, including different mechanisms in different cities in the same country (Table 3).

In Latin America, seven of eight collaborative investigations identified waterborne transmission as a major element of risk for epidemic cholera (Table 3). Waterborne transmission occurs when feces from an infected person contaminate a stream, lake, or shallow well used for drinking water; when municipal water supplies draw from a contaminated source; or when water that was initially clean is contaminated during or after distribution. Water pipes are often laid in the same trench as sewer pipes. If water pressure drops, because of an intermittent water or power supply, then the low pressure in the water pipes can draw sewage into the water through minute inadvertent cross-connections. In this

way, a few cases of cholera that contaminate sewage can multiply rapidly into a citywide epidemic. Authorities who limit their monitoring to the initial quality of water going into the piping system at the wellhead may see no need for chlorination.

Because water is rarely available 24 h a day in many municipal systems and is often collected from shared public standpipes in the developing world, drinking water is usually stored in the home. If the vessel used to store water has a wide mouth and if water is removed by scooping it out by hand, stored water is likely to be further contaminated. Increasing water contamination was measured in Trujillo, Peru in 1991: fecal coliform counts were 1 per 100 ml in water collected at the wellhead, 2 per 100 ml at public taps, and 20 per 100 ml in water stored in the home.[115] This phenomenon was further clarified in a systematic review of the relationship between water quality at point of use and both cholera and general diarrhea. Water quality was measured by coliform counts and this analysis found that while interventions involving the treatment and storage of water were not protective against general diarrheal diseases, such measures did clearly reduce the burden of illness attributed to cholera.[116] Protective practices include using a small-mouthed vessel to store water, pouring water from the vessel rather than scooping it out, treating water in the home with chlorine or by boiling, or adding citrus juice to the water to acidify it.[117]

Foodborne transmission can also occur, particularly through moist grains such as rice or millet and by seafood. Transmission by foods other than seafood was identified in four of eight collaborative investigations in Latin America (Table 3). When leftover moist grains are held at ambient temperature, a few vibrios can grow to a large dose by the next meal. The risk depends on the sauces that accompany the grain. In Guinea, cholera was associated with the use of a peanut sauce with neutral pH, while an acidic tomato sauce was highly protective.[118] In Mali, cholera was transmitted by millet, a grain that usually would have been made with acidic fermented goats' milk. Because of drought, the goats were dry, and the millet permitted survival of vibrios.[72] Transmission has occurred from fruits and vegetables, which have been documented to have been irrigated with fresh sewage or splashed with sewage on the way to market.[117] *Vibrio cholerae* can be transmitted in street-vended foods and beverages, which are often prepared in unhygienic ways and then held for many hours at ambient temperatures. In Piura, Peru, street beverages made with contaminated ice were an important source of cholera.[92] In Guatemala, frozen fruit drinks were the dominant source.[63]In Zambia, the consumption of raw vegetables was associated with cholera. Interestingly, these investigators found that the consumption of kapenta, a dried sardine-like fish, and the presence of soap in the home, were protective.[119]

Seafood can be an important source of cholera in the developing world when shellfish are harvested from heavily contaminated waters and processed with little regard to sanitation. Transmission of cholera through seafood occurred in two of eight collaborative investigations in Latin America (Table 3). Vibrios can easily survive light cooking and then grow to an infectious dose if the seafood is held for several hours at ambient temperature. In Guinea-Bissau, cholera was associated with eating small crabs, particularly as leftovers.[81] In Peru, ice used to ship fish was not made from chlorinated water in 1991, because "it was not for human consumption," although the fish were typically eaten without cooking.[92]

In the urban developing world, it is typical to find multiple layers of transmission occurring simultaneously. For example, in Manila, cholera was associated with municipal water contaminated at the periphery of the distribution system, and with street-vended foods.[120] One common implicated street food was a mussel soup made of shellfish harvested from aquaculture in a contaminated bay.

Food served on international flights has twice been implicated as the cause of cholera outbreaks. One outbreak occurred in 1972, on a flight from Great Britain to Australia, and a larger outbreak occurred in 1992, affecting 75 passengers, on a flight from Argentina to Los Angeles, via Peru.[121,122] Following the latter, in which cold seafood salad served enroute from Peru was epidemiologically associated with infection, the Centers for Disease Control and Prevention (CDC) advised the International Air Transport Association to stock oral rehydration solutions on international flights and to avoid serving cold salads or hors d'oeuvres prepared in cities with cholera epidemics.[123]

Transmission of *V. cholerae* O139 has not been well studied, but is likely to be similar to that of O1. Repeated isolation from water suggest that waterborne transmission is likely. A case–control study, which included cases of both O1 and O139, demonstrated similar modes of transmission among these two serogroups, including the consumption of untreated water and raw seafood.[124]A retrospective cohort study to assess the source of a *V. cholerae* O139 outbreak on a cruise ship found that illness was associated with eating yellow rice at a buffet in Thailand.[125]

7. Pathogenesis and Immunity

The severity of symptoms varies with the dose of bacteria ingested, the effect of gastric acid, and the patient's blood type (see Sections 5.7 and 5.11). In volunteer feeding trials,

ingesting 10^6 organism with bicarbonate buffer or mixed in food regularly results in severe diarrheal illness, whereas doses of 10^9 or more are needed if the vibrios are consumed in water without buffering gastric acidity.[126] Lower doses may result in severe illness if the bacteria are protected by the buffering action of food or if little gastric acid is present for other reasons.

Following ingestion, the bacteria pass through the stomach and reach the small intestine. In that alkaline and bile-rich environment, they attach to mucosal cells and produce cholera toxin. Toxin production is regulated by sensors that react to the surrounding environment. Once toxin is produced, the toxin B-subunits bind to specific ganglioside GM_1 receptors on the surface of intestinal mucosal cells.[127] A portion of the A subunit enters the cell and activates adenylate cyclase, producing high levels of cyclic AMP in the cell and active pumping of chloride ion into the intestinal lumen. As Cl^- is pumped into the intestine, potassium, bicarbonate, and water follow passively. The intestines fill with an alkaline, salty fluid, which is an ideal growth medium for *V. cholerae* which do not invade, and remain within the gut. Diarrhea begins when the colon cannot absorb the fluid fast enough and can reach 1 L/h. For a 70-kg adult, this represents a loss of 10% of body weight in 7 h, unless fluids and electrolytes are replaced. Fluid loss leads to decreased blood pressure, and finally circulatory collapse. Loss of bicarbonate leads to a profound metabolic acidosis, with blood pH below 7.0. Loss of potassium leads to neuromuscular malfunction, painful muscle cramps, and ultimately to cardiac arrhythmia, which may be the terminal event.

Rapid replacement of lost fluid and electrolytes is the critical lifesaving treatment.[128] For the most severe cases, this is done with intravenous polyelectrolyte fluids such as Ringer's lactate. Oral rehydration solution (ORS), a carefully defined mixture of carbohydrate and electrolytes, should be used to replace losses in patients who are able to drink, saving lives for pennies. This low-cost treatment is widely available throughout the developing world as WHO ORS or UNICEF Salts and represents a major breakthrough in the treatment of cholera and other dehydrating diarrheal diseases. Standard packets of either glucose-based or rice-based solutions are mixed with a standard volume of potable water and drunk to prevent or correct volume depletion. The presence of the proper amount of carbohydrate drives absorption of the electrolytes by the bowel mucosa. The optimal composition of ORS has been a matter of recent debate. Rice-based ORS have been shown to result in a greater reduction of stool output than glucose preparations.[129] In an attempt to improve the efficacy of ORS, reduced osmolarity solutions were further studied. A systematic review of ORS among a pediatric population found that the reduced osmolarity solution was associated with reduction in stool output, vomiting, and intravenous fluid use.[130] Based in part on these findings, the WHO, in 2002, advocated for reducing the osmolarity of the solution from 311 to 245 mOsm/L. Although the reduced osmolarity solution, in the above study, did not result in a significantly different serum sodium level, there has been concern regarding the possibility of ORS-induced hyponatremia and subsequent sequela.[131]

An additional concern regarding ORS is the water used to make the solution. As a result of being prepared from unclean water or of improper handling, ORS is often contaminated by enteropathogenic bacteria.[132]Disinfecting the water used to prepare ORS with bleach and storing the solution in narrow-mouth vessels was found to prevent bacterial contamination.[133]

Antibiotic treatment, for example, with tetracycline or trimethoprim–sulfamethoxazole, is a useful adjunct to fluid therapy, as it decreases fluid losses and hastens recovery, but it is not sufficient treatment by itself. For those with a contraindication (e.g., resistant strains or allergy) to the above antibiotics, the use of ciprofloxacin is an alternative.[134,135] A recent study found that a single dose of ciprofloxacin was as effective as a 3-day regimen of erythromycin among pediatric population.[136]

The diarrhea decreases after a few days of vigorous fluid therapy, and the patient recovers as soon as the fluid and electrolyte deficits are corrected. The diarrhea stops even though the intestines are still filled with toxigenic *V. cholerae*. Following infection, the patient is resistant to subsequent challenges with *V. cholerae* O1, but this protection is less than perfect and may not last for more than a few years. Infection with classical strains provides nearly complete protection against subsequent infection with any *V. cholerae* O1, while infection with E1 Tor strains provides only 60–70% protection to subsequent infection with either biotype.[37] This less solid immunity may help explain why the seventh pandemic has lasted so much longer than pandemics five and six. This is also the reason that vaccines are developed from classical strains, even though they are intended to protect against E1 Tor. Infection with O1 strains appears to provide no subsequent protection to infection with *V. cholerae* O139, although both produce the same toxin. This suggests that antitoxic immunity plays little role in the protective response.

8. Patterns of Host Response

8.1. Clinical Features

The clinical features of cholera are the result of a profound loss of intravascular fluids and electrolytes. The illness begins as a watery diarrhea, accompanied by abdominal

cramps, that typically starts 24–72 h after ingestion of the organisms. The diarrhea becomes voluminous and in severe cases continuous. The feces are like clouded water, with flecks of mucus, and are inoffensive smelling. They have been described since Osler's time as "rice water" stools, but could better be described as looking like thin chicken rice broth. As electrolyte disturbances become more pronounced, acidosis leads to vomiting and hypokalemia produces agonizing leg cramps, particularly in older patients. The signs and symptoms of dehydration are pronounced once fluid losses exceed 5% of body weight: dry mouth, absence of tears, increasing thirst, and loss of skin turgor, leading to the so-called "washer-woman's hands." As fluid losses reach 10% of body weight, the blood pressure drops and the patient becomes obtunded, nearing death from vascular collapse. Fever is rarely pronounced, and the patient's sensorium remains clear until the very end. The disease is reversible up to the moment of death, if fluid and electrolyte losses can be vigorously replaced. Transient renal failure may follow rehydration. Cholera can be particularly severe in the pregnant woman, and loss of the fetus is likely if infection occurs in the third trimester.[137] No increase in severity has been described among persons infected with human immunodeficiency virus (HIV).

Clinical manifestations of infection with *V. cholerae* O139 Bengal are similar to those of *V. cholerae* O1. However, several episodes of bacteremia have been documented with *V. cholerae* O139, as well as a case of subsequent reactive arthropathy.[124] It is possible that this organism is more invasive than *V. cholerae* O1, perhaps because of the capsule present in O139 strains.

8.2. Diagnosis

Diagnosis is made by isolation and identification of the causative organism or by demonstrating a diagnostic increase or decrease in the antibody response. In the outbreak setting, persons with similar illnesses may be presumed to have cholera once the etiology of the illness is established for a representative sample.

In the United States, cholera should be suspected and appropriate stool cultures requested from anyone with severe diarrheal illness who recently traveled to the developing world or who has ingested raw shellfish or undercooked crab.

In the developing world, in the setting of a known or threatened epidemic, presumptive diagnosis is made on clinical grounds. The report of two or more adults in the same place with severe watery diarrhea and vomiting or the report of an adult dying of watery diarrhea may be presumed to be cholera until proven otherwise. Immediate action should be taken to bring adequate supplies for treatment, prevention, and diagnosis to that location and to warn surrounding villages of the possibility of cholera.[11] A small number of rectal swabs from persons with fresh diarrheal cases should be collected and transported in Cary–Blair transport medium to a competent laboratory.

9. Control and Prevention

9.1. General Concepts

Toxigenic *V. cholerae* is unlikely to be eradicated, as it is likely to persist indefinitely in environmental reservoirs. Crowded urban populations in the developing world provide the setting for future epidemics of cholera when the organism is introduced, and increasing international mobility makes such introductions likely. As long as the organism persists anywhere, the potential for cholera exists wherever conditions are ripe for sustained transmission.

However, epidemic cholera can be prevented. Avenues of sustained transmission have been closed already in many parts of the world. Between 1961 and 1991, 56 travel-associated cases were reported in the continental United States without subsequent spread.[57] Between 1995 and 2000, 61 cases of cholera, 37 (61%) of which were acquired abroad, were reported in the United States.[108] Again, with the possible exception of a single case, subsequent spread did not occur.[110] In the United States and other industrialized nations, when a case of cholera occurs, prompt public health action is still warranted to determine the source of infection and to be sure that the feces are properly disposed of. Routine sanitation is adequate to prevent further transmission in most areas, but for some populations, including the homeless, the "colonias" along the Mexican border, and a few Native American reservations, the potential for further transmission still exists. Most populations on the North American and European continents are protected by the engineering triumphs of the "Sanitary Revolution," i.e., safe water and sewage treatment systems. Similar efforts now beginning could control cholera by the early 21st century in many rapidly developing countries of Asia and Latin America.[7]

In the rest of the developing world, where industrialization is slower, cholera prevention is an increasing challenge. A targeted health education effort may prevent illness and death by stressing the need for careful water and food handling and the need to seek medical care promptly for diarrheal illness. Emergency control measures such as boiling water are difficult to sustain. Large-scale engineering solutions are too costly to build and maintain, and there is a

critical need for simpler alternatives. Some promising strategies are being developed and tested. For example, because storage of drinking water in the home is nearly universal in the developing world, modification of the storage vessel to keep stored water from becoming contaminated is a simple and inexpensive strategy.[138,139] During an outbreak investigation on Ebeye Island, Republic of the Marshall Islands, researchers found that even chlorinated water could become contaminated, likely occurring during the transport and storage process, while using a tightly sealed container to haul water was protective.[140] A study in Kolkata found that cholera infection, as detected by stool culture, was less common among families using either "sorais", a narrow necked earthenware pitcher, or chlorine tablets, when compared to control families.[141] Sorais are designed such that the water must be poured out, rather than being scooped out by hand.

Drinking water can be disinfected routinely in the house at the "point of use".[139]In remote areas, a simple apparatus can produce a disinfectant chlorine solution by electrolysis of salt water, using solar power. With one such machine, a village of several thousand people can treat their own drinking water and make a net profit selling surplus disinfectant to their neighbors. Point of use chlorination effectively reduced the risk of cholera in Madagascar with a protective OR of 0.1.[142]Larger ventures to produce a water disinfectant product for routine use in the developing world are of potential commercial interest. Production of inexpensive chlorine-based disinfectants for household drinking water, linked to social marketing, is now occurring in 19 countries in the developing world.[143] Two studies have shown the benefit of solar disinfection of drinking water.[144,145] A recent study revealed that although there was no significant benefit of solar disinfection on cholera in adults, a clear benefit was seen in children under age 6 years. In this study, solar disinfection was performed by placing water in a clear, plastic bottle and leaving it on the roof, a procedure requiring minimal additional resources.[146] Closer attention to ice production in the developing world can guarantee that treated water is used to make ice, the cheapest of modern luxury goods.

Simple improvements in food preparation may also greatly reduce the risk of cholera. Acidification of sauces is routine for reasons of taste in many cultures and can be further promoted by public health authorities: tomatoes, tamarind, lemons, lime juice, and yogurt can all acidify foods sufficiently that *V. cholerae* cannot survive.[147,148]Even the use of powdered drink mixes, which contained citric acid and possibly ascorbic acid, was found to provide protection against cholera.[140] Foods can be made safer by thorough cooking, by heating or at least acidifying leftovers, and by avoiding raw seafood harvested from dubious waters. Particular attention to the problem of street vendor sanitation can include providing safer carts; promoting the use of clean water, soap, and disinfectants; training street vendors in the elements of food safety; and educating the consumers to look for vendors who are following simple and visible precautions.[149]

In many parts of the world, raw or undercooked seafood is a staple source of protein. Taking precautions to protect harvest waters and using clean water for processing and clean ice for shipping can help prevent seafood-borne cholera. However, as long as shellfish from warm waters are consumed raw, an irreducible minimum number of cases can still be expected because of the natural estuarine reservoirs of toxigenic *V. cholerae*.

When an epidemic of cholera appears, the first priority is to prevent death by assuring adequate treatment and by educating the population to seek treatment rapidly once a diarrheal episode begins. The success of efforts to control the epidemic depends on knowing the actual vehicles of transmission and having the tools available to block them. Because the vehicles may vary, swift epidemiological investigation, including a case–control study, may be critical to guide control efforts. In 1991, in Santiago, Chile, for example, case investigation suggested that cholera was being transmitted through use of fresh sewage to irrigate salad vegetables; halting this practice brought an abrupt end to this specific outbreak as well as decreasing typhoid fever incidence by 90%.[150] In 1974, in Portugal, successful control followed the identification of two sequential vehicles: contaminated raw shellfish and a spring used to make bottled water.[113,114] Throughout Latin America, recommendations to boil water and to avoid street-vended foods and raw seafood followed the identification of these routes early in the epidemic. Such emergency changes are not sustainable, and the persisting epidemic demands more fundamental approaches to prevention.[70]

9.2. Antibiotic and Chemotherapeutic Approaches to Chemoprophylaxis

Antimicrobial prophylaxis plays a limited role in the control of cholera. Prophylactic treatment of family members of cholera patients in the Philippines was shown to decrease the incidence of infection from 13% in the untreated group to 0% in family members taking 20 doses of tetracycline over 5 days.[151] In closed settings, such as prisons, ships, or small and isolated villages, the strategy has potential merit. However, chemoprophylaxis on any scale runs the risk of evoking antimicrobial resistance. Early in the West African epidemic, an extravagant "cordon sanitaire" strategy

included forced antimicrobial treatment of all who passed through roadblocks. This had no discernible effect on the progress of the epidemic, but resulted in widespread sulfa resistance in vibrios and avoidance of established roads. In Latin America, where the practice has been to avoid chemoprophylaxis, the organism remained generally susceptible in 1995, after a million cases had been reported. An instructive exception was in Guayaquil, Ecuador, where a vigorous campaign of family chemoprophylaxis in 1991 was associated with rapid emergence of multiple resistance, which forced the strategy to be abandoned.[152] In addition to the risk of causing the emergence of resistant strains and the substantial cost of antibiotics used in this way, mass chemoprophylaxis with sulfa or tetracyclines has been associated with severe adverse reactions to the drugs and with the appearance of folk belief that the antibiotic is a form of vaccine that confers permanent protection.

9.3. Immunization

In the past two decades, considerable progress has been made in the development of both live and killed oral cholera vaccines (Table 4).

Parenteral vaccines have historically not been favored given the low efficacy and high side-effect profile. A parenteral cholera vaccine licensed in the United States was withdrawn from production and sale in 2000. Although research has focused on the development of effective oral vaccines, as yet no vaccine is available that has broad public health applicability. Efforts to develop such a vaccine have been ongoing for more than a century as an inexpensive cholera vaccine that provided long-term protection against cholera would be an important public health tool.

Currently two vaccines are now available in some countries, although neither are licensed in the United States. These are an oral whole-cell killed *V. cholerae* O1 vaccine that includes a recombinant B-subunit of cholera toxoid (WC/rBS)[8], and an oral bivalent vaccine, currently available only in Vietnam, consisting of a mixture of heat and formalin killed O1 and O139 *V. cholerae* strains.[153] A live, attenuated genetically modified vaccine, CVD 103-HgR,[154,155] previously marketed as Mutachol, has recently been discontinued.

When WC/rBS was tested extensively in a field trial in Bangladesh in a location where both E1 Tor and classical strains were present, it had a protective efficacy in the first year of the trial of 62%.[156] Efficacy waned after 2 years, and was substantially lower among persons of blood group O,[157] among children, and against infection with E1 Tor biotype as opposed to classical biotype.[158] In order to assess the protective effect on herd immunity, data from the above studies were reanalyzed. Although vaccine coverage rates varied, herd protection was observed, accounting for a fraction of the observed efficacy.[159] In a subsequent trial among Peruvian military recruits, short-term efficacy in protecting against E1 Tor cholera in the first 2 months after vaccination was 86%.[160] A recent study assessing the effectiveness of this vaccine among a population with a high prevalence of HIV/AIDS in Mozambique revealed similar results.[161] This vaccine was found to offer 78% short-term protection against more severe cholera. Such short-term protection rates may be helpful in preventing outbreaks of cholera. The duration of this protection is currently under investigation.[162]

The efficacy of the CVD 103-HgR vaccine was measured in volunteer challenge studies conducted in North America. Efficacy is 62–64% against any diarrhea when challenged with E1 Tor strains and 100% when challenged with classical strains.[154] Duration of protection has been documented out to 6 months, but has not been tested beyond that. Curiously, the antibody response to CVD 103-HgR is higher in persons with blood group O, though it is unclear whether they are better protected.[155] A small trial in Mali found that a single dose of this vaccine was safe and immunogenic in both HIV and non-HIV infected individuals.[161] This single-dose immunization, given its relative high level of early protection, has been a candidate for use during an outbreak, however is not currently available on the market due to discontinued production.

The vibriocidal response of the bivalent, anti-O1, anti-O139 whole-cell vaccine was evaluated in Vietnam. This two-dose regimen was directly compared with the WC/rBS

Table 4. Characteristics of Cholera Vaccines Now in Commercial Production

Characteristic	Type	Route	Number of doses	Time to complete primary series	Efficacy	Duration
Whole cell/B-subunit	Killed organisms/ B-subunit of toxin	Oral	3[a]	12 weeks[a]	62% at 1 year[a,b]	2 years
Whole cell	Killed organisms	Oral	2			

[a]In Bangladesh field trials. Recent field trial in Peru used two doses at 1- to 2-week intervals, and obtained efficacy at 1–2 months of 86%.[154]
[b]Against both classical and E1 Tor strains. Protection against E1 Tor alone was reported to be lower.

in both an adult and pediatric population. A rise of at least fourfold anti-O1 vibriocidal response was noted in nearly 60% of recipients, similar to the response elicited by WC/rBS. The serum anti-O139 response was smaller, however, both responses were greater in children than adults.[153]

Historically, cholera vaccine has not been used successfully as a control measure in the epidemic setting. The risk of cholera is immediate, whereas protection afforded by vaccines begins a week or two after completion of the primary series. In an extreme example, the cholera epidemic that occurred among refugees at Goma, Zaire, was largely over in 4 weeks, before a two-dose WC-BS vaccine could have provided protection, even had a vaccine campaign commenced the day the camp was created. The single-dose administration of CVD 103-HgR makes it a more feasible option. Indeed, during a cholera outbreak in Pohnpei Island, Micronesia, in 2000, the government attempted to use a mass immunization strategy to limit the spread of disease. Nearly 50% of the population was vaccinated with a retrospective calculated vaccine efficacy of 79%.[163] The rate of suspect cholera was five times lower among those who received the vaccine when compared to their unvaccinated counterparts. Although traditional hygiene control measures continue to be the most effective method of limiting the spread of cholera, the evidence in Micronesia suggests that mass vaccination may have a complementary role.

The availability of vaccines leads to pressure to use them, and the issue illustrates what to expect when partially effective vaccines become available for other feared diseases such as acquired immunodeficiency syndrome (AIDS). Humanitarian impulses, coupled with the need for public health departments to "do something," encourage cholera vaccination campaigns. However, experience has shown that once a campaign is launched, pressure to vaccinate everyone can be irresistible, and scarce public health resources are diverted from other critical activities. It will be difficult to convey the notion of partial protection to a population accustomed to thinking of vaccines as "magic bullets"; vaccines may falsely believe themselves to be completely protected and may ignore other prevention advice. Vaccination is not the only means of preventing cholera, and needs to be shown to be less expensive and more effective than other strategies for preventing cholera before it can fulfill its full potential as a public health tool.

10. Unresolved Problems

Fundamental questions about the nature of the environmental reservoir remain unanswered. We do not know the nature of these niches, nor how *V. cholerae* persists from one season to the next, nor what determines the sharp seasonal increases in disease. The failure of the Latin American epidemic to even appear in the Caribbean suggests there could be an ecological resistance to introduction. The role of bacteriophage in bringing epidemics to an end, debated since the 1930s, remains to be defined and exploited.[74] Better ecological understanding may lead to improved prevention strategies.

Major questions remain about the bacterial pathogen itself. The mysterious advance and decline of the classical biotype of *V. cholerae* O1 and the potential for competitive interactions among the various strains are of great potential importance. Will *V. cholerae* O139 Bengal persist and continue to spread, becoming the eighth pandemic? The microbial characteristics that permit epidemic spread are undefined. The appearance of *V. cholerae* O139 shows that immunologically important changes can occur in the O-antigen without altering epidemic potential. The appearance of *V. cholerae* O139 offers a case study in the evolution of bacterial serotypes in general. This may be a bacterial example of "antigenic escape" mutation, like the changes that occur regularly in influenza viruses, an evolutionary response by a pathogen to high levels of immunity. Does this change allow this organism to spread more rapidly in a population that was previously immune to cholera because of repeated exposure to O1 strains? Will it continue to spread in less immune populations, where it may have less of an advantage over O1 strains? Will *V. cholerae* O141 cause an epidemic?

Many questions remain unresolved about cholera in relation to the human environment. The development of specific and sustainable control measures is a continuing challenge. Appropriate technologies for water treatment and storage, for sanitation, and for safer food handling are likely to have a direct impact on cholera as well as on a variety of other diseases transmitted through contaminated water and food. In 1854, John Snow demonstrated that water pipes were dangerously efficient at delivering cholera throughout London. Now, throughout the developing world, poorly maintained urban water systems are just as dangerous. Rebuilding such systems depends on the confidence and participation of people in their local government, as well as on the funds for construction and repair. The development of sustainable and locally controlled means of water treatment, such as the combination of better water storage vessels and water disinfection by the consumer at the point of use, may be an interim solution that can help communities gain experience in providing necessary services for themselves.

The search for better cholera vaccines is accelerating. We are soon likely to have a substantially improved understanding of virulence mechanisms and of the nature of the protective immune response. Vaccine research is hampered

by the lack of an animal host (so that volunteer trials are inevitable) and is now complicated by the appearance of *V. cholerae* O139. Vaccines may now need to be polyvalent, providing protection against both O1 and O139 serogroups. However, continued progress means that promising vaccines are available, with others on the horizon, and the goal of sustained protection may be achievable.

Epidemic cholera is an indicator of severe underdevelopment, a sign that the basic sanitary infrastructure of a society is below a critical threshold that guarantees its citizens safe water and sewage disposal. In late 2008, Zimbabwe experienced one of the largest cholera outbreaks reported to date. As of February 16, 2009, over 75,000 cases of cholera and 3,600 deaths have been recorded. A host of factors, including a deteriorating health infrastructure, decreased awareness regarding the prevention and treatment of cholera, and a delayed outbreak response, are to blame.[164,165] Communities that make the necessary investments will prevent this and many other diseases that are transmitted through the same routes. Bringing about this investment worldwide, a sustained global "Sanitary Revolution," is a central challenge for global public health in the 21st century. The scope of cholera prevention extends beyond public health and clinical medicine to include fisheries, agriculture, shipping, and tourist industries of many nations. Just as cholera spurred the development of sanitary reform and modern public health in Europe and America, so epidemic cholera is likely to be less and less tolerable in the growing democracies of the developing world.

CHAPTER 13

Clostridium difficile

Dale N. Gerding and Stuart Johnson

1. Introduction

Clostridium difficile produces gastrointestinal infection in humans and animals, ranging from asymptomatic colonization to diarrhea, pseudomembranous colitis, toxic megacolon, colonic perforation, sepsis, and death. *C. difficile* has emerged as a major cause of nosocomial diarrhea and is the most frequently identified cause of hospital-acquired infectious diarrhea in patients.[1,2] *C. difficile*-associated disease (CDAD) is a general term used to describe the illness caused by this organism, which is usually diarrhea, but also includes abdominal pain, fever, and absence of diarrhea. Pseudomembranous colitis (PMC) is a descriptive term for the inflammatory colitis with grossly visible colonic exudate composed largely of proteinaceous material and cellular debris. *C. difficile* is the most commonly identified cause of PMC. Not all patients with CDAD have PMC, but PMC is considered a more severe form of diarrheal illness caused by *C. difficile*. This species has been unprecedented in the bacteriologic world for producing disease almost exclusively in animals or humans who have been exposed to antimicrobial or antineoplastic agents; however, recent reports suggest that some cases may not be associated with antimicrobials and that anti-acid medications such as proton pump inhibitors and H_2 receptor antagonists may predispose to CDAD.[3,4] The relative importance of these agents as risk factors for CDAD and the role of gastric acidity in the host defense against this spore-forming pathogen is not clear.

Dale N. Gerding and Stuart Johnson • Edward Hines Jr. Veterans Affairs Hospital and Loyola University Chicago, Stritch School of Medicine, Hines, Illinois 60141, USA.

2. Historical Background

The historical evolution of the discovery of *Bacillus difficilis* by Hall and O'Toole[5] in 1935 in the feces of asymptomatic newborn infants to the eventual linking of the organism to the new disease, "clindamycin colitis," in the 1970s is a fascinating story of the marriage of an organism without a disease to a disease without an organism. As outlined by Bartlett,[6] three diverse investigative areas, beginning with the first description of PMC by Finney[7] in 1893, the discovery of *C. difficile* by Hall and O'Toole[5], and the description of the rodent model of antibiotic-associated colitis by Hambre et al.[8] in 1943, were critical to the ultimate discovery of *C. difficile* as the major cause of PMC.

Pseudomembranous colitis was recognized historically before antibiotics were discovered and was noted as a rare complication of gastrointestinal surgery. The increasing use of antibiotics was accompanied by an increase of PMC cases. Chloramphenicol and tetracycline were the most frequently implicated agents, but "staphylococcal enterocolitis" was the usual diagnosis based on the Gram's stain evidence of typical gram-positive cocci in the stool. It has not been established whether *C. difficile* was the cause of at least some of this illness, but the subsequent publication of the use of oral vancomycin to successfully treat this disease is provocatively suggestive of the possibility.[9] Pathologically, staphylococcal enterocolitis involved both large and small bowels, whereas *C. difficile*-associated PMC is confined to the colon, so they may be separate diseases as confirmed by documentation of both distinct diseases simultaneously in the same patient.[10] In 1974, Tedesco et al.,[11] using endoscopy, reported an extraordinary high rate of PMC in patients who had received clindamycin, leading to an intensification of the search for the etiology.

The discovery that antibiotics produced lethal illness in guinea pigs and hamsters was first observed by Hambre

A.S. Evans, P.S. Brachman (eds.), *Bacterial Infections of Humans*, DOI 10.1007/978-0-387-09843-2_13,
© Springer Science+Business Media, LLC 2009

et al.[8] using penicillin to treat gas gangrene in guinea pigs. At autopsy these animals demonstrated a consistent finding of a dilated inflamed cecum filled with liquid stool. Although the cause of the illness was vigorously pursued, no etiology was discovered, and the connection of this animal model to human antibiotic-associated enterocolitis was not made. Cytopathic toxicity for cell lines used for viral culture of animal stool extracts and later human stools from patients with PMC led to the mistaken postulate of a viral etiology.[12] Protection of animals challenged with clindamycin by giving them oral vancomycin implicated gram-positive bacteria as causative and led to the postulate of a toxin etiology for the cell cytotoxicity.[13,14] Eventually a clostridial toxin-producing organism was implicated as the cause of both hamster and human diseases.[15,16] Subsequent work disclosed that two large toxins, A and B, are responsible for causing clinical illness and that the majority of clinical illness in humans occurs in hospitalized patients, particularly the elderly.[17]

3. Methodology

3.1. Sources of Mortality Data

Mortality data are based on surveys and reports from multiple hospitals and ranged from 0.6 to 1.5% of patients who acquired CDAD prior to 2000.[18–19] Directly attributable mortality reported with an epidemic strain of *C. difficile* was 6.9% during a multiple hospital outbreak in 2004 in Quebec, Canada.[20]

3.2. Sources of Morbidity Data

CDAD and PMC were not reportable illnesses previously, but are now reportable in Quebec and the United Kingdom. Rates of CDAD are also reported anecdotally in the medical literature primarily from institutional experiences and range from 0.3 to >22.5 cases per 1,000 hospital discharges.[20–25] CDAD rates include cases of PMC, but the proportion of CDAD patients who have PMC is not clear. In one well-studied group of 67 patients with CDAD (diarrhea plus stool culture and toxin assay positive) who underwent flexible sigmoidoscopic examination, PMC was found in 51%.[17] Major morbidity includes colectomy for uncontrolled disease which occurred in 1.9% of patients in the 2004 Quebec outbreak.[20]

3.3. Surveys

Population survey data for CDAD are very limited and serological data are not useful. *C. difficile* stool culture surveys are reported sporadically. Most surveys reveal that less than 5% of stools of asymptomatic adults contain the organism (range 1–15%)[26,27]; however, it is commonly present asymptomatically in infants under 1 year of age (range 15–70%).[8–30]

3.4. Laboratory Diagnosis

3.4.1. Toxin Detection. Detection of cell cytotoxicity in diarrheal stool that is neutralized by the addition of specific *C. difficile* antitoxin prepared from sera of immunized animals (or *C. sordelli* antitoxin, which cross-reacts with *C. difficile* antitoxin) is the most specific diagnostic test for CDAD. Most cell lines used for viral isolation are suitable for detection of the *C. difficile* cytotoxin, toxin B.[31] Proper dilution of the specimen is required for optimal results (dilutions usually range from 1:40 to 1:200); lower dilutions can result in nonspecific cell toxicity and false-positive results. Higher dilutions may result in false negatives.[31] Sensitivity of the cell cytotoxin test ranges from 67 to 100%, somewhat lower than the sensitivity of organism culture.

Commercial enzyme immunoassays (EIA) for the detection of toxin A and/or toxin B are also available and have undergone evaluation and publication in peer-reviewed journals. The EIA test kits employ monoclonal and/or polyclonal antibodies against the toxin(s) for detection. These tests are widely used in US hospitals for the detection of toxin but are less sensitive than cell cytotoxicity and organism culture; however, they can be performed more rapidly.[31] The first generation of EIA tests detected only toxin A and were not able to detect some toxin variant strains. Many clinical laboratories have since switched to EIA tests that detect both toxins A and B; however, these newer assays still may only be 80% sensitive.[32]

3.4.2. Organism Detection. Stool culture for *C. difficile* is the most sensitive laboratory test available, but it is not as specific as cell cytotoxin testing, primarily because there are often many patients in hospitals who are asymptomatically colonized by toxigenic or nontoxigenic strains of *C. difficile*. Culture of *C. difficile* from such a colonized patient who has diarrhea from another cause could be misinterpreted as CDAD. For this reason, confirmation of the ability of an organism to produce toxin in vitro has been suggested as a means to improve the specificity of culture as a diagnostic test in patients who have negative stool toxins or have not had a stool toxin test performed.[31,33] Selective agar medium containing cycloserine, cefoxitin, and fructose (CCFA) is required for the recovery of *C. difficile* from stool specimens; preplacement of CCFA plates in an anaerobic atmosphere for at least 4 hours prior to specimen inoculation enhances organism recovery.[34,35] Stool culture sensitivity is 89–100% and specificity is 84–99%.[31] Stool culture

for *C. difficile* is essential for epidemiological investigation of outbreaks so that organism typing can be performed.

Polymerase chain reaction (PCR) employing arbitrary primers is a sensitive method of organism detection; if the primers are selected from within the toxin gene sequences it is specific for detection of toxigenic *C. difficile*.[36–39] Real time (RT) PCR has recently become available as a diagnostic test and looks very promising as a sensitive, specific and rapid test, but is still undergoing clinical comparative analysis for sensitivity and specificity.

The latex agglutination test for detection of *C. difficile* protein was originally developed to detect toxin A, but subsequently was found to detect another protein, glutamate dehydrogenase.[40,41] Although rapid, inexpensive, and reasonably specific, the sensitivity of this test (58–68%) was too low, but has been improved by the use of an enzyme immunoassay method for detection that has improved sensitivity.[31]

3.4.3. Detection of Pseudomembranous Colitis. Direct visualization by sigmoidoscopy or colonoscopy is the usual method used to diagnose PMC. Small lesions may require biopsy and histological examination for diagnosis. Visualization of PMC is observed in only 51–55% of patients who have diarrhea and have *C. difficile* and its toxin detected in the stool; hence, although endoscopy is essential for the diagnosis of PMC, it is not sufficient to diagnose all cases of CDAD.[17,42]

3.4.4. Pathology. Grossly, PMC appears as a studding of the colonic mucosal surface with white to yellow adherent raised plaques. The distribution of lesions usually includes the whole colon, but it may be variable with occasional rectal sparing. Lesions end abruptly at the ileocecal valve. Microscopically, the membrane is composed of fibrin, mucus, leukocytes, and cellular debris and demonstrates a point of attachment to the mucosal surface. There is a predominantly neutrophilic inflammation of the underlying mucosa, which is typically quite focal and patchy. The superficial epithelium is quite commonly eroded, with necrosis present in the upper half.[43]

4. Biological Characteristics of the Organism (Etiologic Patterns)

C. difficile is a gram-positive anaerobic spore-forming bacillus. Spores are resistant to drying and persist in the environment for prolonged periods of time. The organism is widespread in distribution worldwide and is found in soil, hay, mud, sand, and the stools of multiple animal species including horses, dogs, cats, camels, donkeys, and cattle. The ability of the organism to produce disease is attributed to two large exotoxins: toxin A, with a molecular weight of 308 kDa, and toxin B, with a molecular weight of 207 kDa.[44] Toxin A is a large single-unit toxin that possesses both enterotoxic and cytotoxic properties. Toxin A binds to carbohydrate receptors on the cell surface and mediates toxicity by disruption of the cell cytoskeleton through glucosylation of small GTP-binding proteins of the Rho subfamily. Toxin A is also a potent chemoattractant for granulocytes. The toxin B receptor is unknown, but the toxin is a very potent cytotoxin with a similar or nearly identical mechanism of action to that of toxin A. Toxins A and B exhibit significant homology (44.8% identity) with the major differences at the C-terminus region of putative receptor binding. Most *C. difficile* organisms either possess the genes to produce both toxin A and toxin B or lack both genes. A variety of toxin variant strains of *C. difficile* have been identified and have been documented to cause human CDAD and a toxinotyping system has been developed to describe these variants.[45] Toxinotype VIII strains produce no toxin A, but produce a modified toxin B (A-B+ strains) and are capable of causing the full spectrum of CDAD disease, including fatal PMC.[46] The prevalence of toxinotype VIII strains in most hospitals is probably low,[47] but they have caused CDAD hospital epidemics worldwide and are not detected in laboratories that only use toxin A EIA tests for diagnosis.[48,49]

A major CDAD epidemic in the United States, Canada, and Europe has been caused by a toxinotype III variant strain of *C. difficile* that also produces a binary toxin (actin-specific ADP-ribosyltransferase) in addition to toxins A and B and has a deletion in the *tcdC* gene, a putative negative regulator of toxin A and toxin B production.[20,50] These strains have been associated with increased mortality and morbidity and produce about 20 times as much toxins A and B in vitro as standard *C. difficile* strains.[51] Strains that lack the ability to produce toxins entirely are not considered to be pathogenic and have not been associated with clinical illness.

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

There are relatively few studies of the incidence of CDAD in the community setting. Most studies have been conducted in hospitals or chronic care facilities. One community-based retrospective cohort study of members of a health maintenance organization identified a CDAD incidence of 7.7 per 100,000 person-years.[52] The rate of disease resulting in hospitalization was 0.5–1.0 per 100,000

person-years and is comparable to the rate of 1.4 per 100,000 person-years published earlier.[53] Two studies from Perth, Australia, have determined the proportion of community-acquired diarrhea that is caused by *C. difficile* using stool specimens submitted to a central laboratory by general practitioners in the community as a denominator.[54,55] The incidence of *C. difficile* was 5.5% in the first study, 2.6% in the first phase of the second study, and 10.7% in the second phase following an educational program for the referring physicians.[54,55] *C. difficile* was the most common or second-most common pathogen isolated in the two studies. Anecdotal observations in the United States suggest more severe CDAD in previously low-risk populations (peripartum women and community residents), and a primary care database study in the United Kingdom suggests that community-associated cases of CDAD are increasing.[4,56] Both these observations require validation.

The incidence of CDAD in hospitals is considerably higher than in the community and has been studied in two large teaching hospitals over a 10-year period. At the Minneapolis Veterans Affairs Medical Center, the annual CDAD incidence between 1982 and 1991 varied from 3.2 to 9.9 cases per 1,000 patient discharges (0.30–0.71 per 1,000 patient days).[18,25] A remarkably similar incidence was found at the Sir Charles Gairdner Hospital in Perth from 1983 to 1992, where the annual CDAD rate ranged from 0.22 to 0.55 per 1,000 patient days.[57] Both hospitals had active laboratory detection programs utilizing both culture and cytotoxin testing, but the US hospital had a more rigorous CDAD clinical correlation with patient symptoms. Virtually all patients were adult males in the veterans hospital population. A 1997 survey of 18 Canadian hospitals found an incidence of CDAD of 6 cases per 1,000 discharges, contrasting sharply with the rate of 22.5 per 1,000 discharges in 12 Quebec hospitals during an outbreak with the epidemic strain in 2004.[19,20]

Prevalence data are available for the presence of *C. difficile* in stool specimens of persons without diarrhea. For healthy adults, the prevalence rate of asymptomatic*C. difficile* carriage has been found to be under 3%.[26,30] Prevalence of *C. difficile* in a home for the aged (mean age 86 years) on three surveys was 2.3, 2.1, and 8.1%, respectively, whereas in an adjoining chronic care hospital it was 14.7, 7.1, and 10.2%, rates comparable to other reports of residents of long-term care facilities.[58] A point prevalence rate of 10.8% was found in a survey of 340 asymptomatic adult patients in the acute care Minneapolis Veterans Affairs Medical Center (D. Gerding, unpublished). The prevalence of *C. difficile* in the stool of infants under 1 year of age ranges from 15 to 70%, decreasing to adult levels by the age of 3 years.[28–30]

5.2. Epidemic Behavior and Contagiousness

Epidemics have not been described outside of institutional settings. In general, only individuals who have received antimicrobial or antineoplastic agents are susceptible to CDAD. Reports of CDAD in association with proton pump inhibitors or in the absence of antimicrobials are of concern and should be confirmed with more studies.[4,56] Epidemics within acute and chronic care institutions are well described and have been attributed to a single predominant strain of *C. difficile* as well as to several strains present simultaneously.[20–22,59–61] Outbreaks are characterized by culture of the organism and typing by a variety of methods, which include DNA restriction endonuclease analysis (REA), pulsed field gel electrophoresis, arbitrary-primed PCR, PCR ribotyping, and immunoblot methods.[20–22,37–39,50,51,59,60] Contagiousness has been difficult to assess because of the variable susceptibility of exposed persons, the widespread environmental distribution of the spores in epidemic settings, and the possible variable virulence characteristics of the organism. Animal studies indicate that the spore inoculum required to produce disease is <100 colony-forming units (CFU) in susceptible hosts who have received antimicrobials.

5.3. Geographic Distribution

C. difficile and CDAD are considered to be worldwide in distribution, but documentation of rates in many Asian and African countries has not been established.

5.4. Temporal Distribution

No seasonal variation in the incidence of CDAD has been identified, although hospital case rates frequently rise in the winter respiratory infection season in the Northern Hemisphere, possibly related to increased antimicrobial use.

5.5. Age

The presence of *C. difficile* in stools is highest for children under 1 year of age, but these children are nearly all asymptomatic.[28–30] The rate of CDAD has been found to increase with age, being highest in the eighth and ninth decades.[20,26,57] The rate of cytotoxin found in stools was also shown to be highest in the ninth decade.[26] McFarland et al.[62] identified increased age as a risk factor for CDAD, with a relative risk of 11.77 (2.46–56.39, 95% CI) from ages 61–73 years and with a relative risk of 14.30 (3.27–62.51, 95% CI) over the age of 75 years. This was confirmed by Loo et al.[20] who found the CDAD rate to be 74.4 per 1,000 discharges for hospitalized patients in their nineties.

5.6. Gender

Women were found to have significantly higher rates of CDAD between ages 21 and 50 years and over the age of 70 years in one study.[26] In another large hospital study, the ratio of females to males with CDAD was 1.6:1 for ages 40–59 years and 1.7–2.2:1 over the age of 70 years,[57] despite ratios of female to male patients of 0.9:1 in all but the highest decade. Other studies have shown no difference in CDAD rates between the sexes.[23,62] A large case–control study of 237 patients in Quebec hospitals had 48.5% male patients which was not statistically different from the control group.[20]

5.7. Race

No race-specific attack rate data for CDAD are available. Fecal isolation rates for a Japanese population were higher (15%) than in Sweden (1.9%).[26,27]

5.8. Occupation

No occupational data regarding risk are available. Health care workers have not been noted to be at increased risk of CDAD, although sporadic cases in health care employees do occur, almost always in association with antimicrobial use. Health care workers do not have an increased rate of asymptomatic *C. difficile* colonization.[17,63]

6. Mechanisms and Routes of Transmission

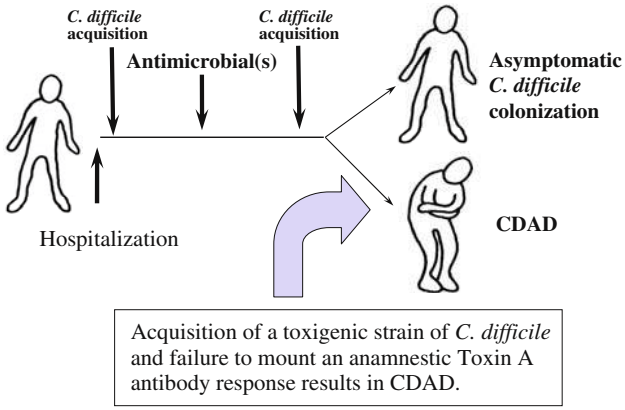
The exact route of transmission is not known, but is assumed to be by way of oral ingestion of *C. difficile* spores, which are found in water, soil, and animal feces. Nosocomial transmission accounts for the majority of CDAD cases reported in the literature. Two potential reservoirs for spread to patients are known: infected patients (symptomatic and asymptomatic) and a contaminated environment including inanimate objects. Infected patients, the environment, and health care workers are intertwined in the nosocomial transmission process, with hand contamination of health care workers correlated with environmental spore contamination, but the exact mechanism(s) by which transmission occurs still remains obscure.[64] It is well documented that patients acquire *C. difficile* in the hospital after being admitted free of the organism.[21,22,65] The rate of acquisition over time has been shown to be linear at about 8% per week on one ward of a hospital with an annual CDAD rate that varied from 3.2 to 9.9 cases per 1,000 discharges.[65] Most of these acquisitions occur asymptomatically.[21,22,65] Asymptomatic stool carriage of *C. difficile* in hospitals with this rate of CDAD has been found to be approximately 20% of all admitted patients.[17,21,22,65] By using genetic typing techniques, it has been shown that the frequency of CDAD among patients who acquire *C. difficile* in hospital is dependent on the strain acquired, but that even highly virulent strains are asymptomatic in the majority of patients.[22] Admissions of *C. difficile*-colonized patients to a hospital ward were associated temporally with the subsequent acquisition of the identical strain by other patients already in the ward.[65]

The hospital environment is contaminated with *C. difficile* spores in proportion to the status of the patient in the environment: lowest around patients who are free of *C. difficile*, intermediate in rooms of patients asymptomatically colonized, and highest in rooms of patients who have CDAD.[21,66] Persistence in the environment has been documented for 5 months.[66] Inanimate objects in the environment have been implicated as the source of transmission, including contaminated commodes, bathing tubs, and rectal thermometer handles.[67–69]

The hands of hospital personnel have been found to be contaminated with *C. difficile*, and several lines of evidence suggest that personnel contamination of the hands may be an important means of transmission.[21,66] In one outbreak, six of seven new cases of CDAD caused by a specific *C. difficile* strain occurred in patients cared for by the same surgical team caring for a long-term colonized patient with a colostomy.[22] A controlled trial of the use of vinyl gloves by health care personnel handling body substances showed a significant decrease in new CDAD cases, suggesting hands as a means of transmission.[70] It is not clear how personnel' hands become contaminated, as both the patients and their environment could be the source.

7. Pathogenesis and Immunity

We postulate that at least three factors are required for CDAD to occur: (1) antimicrobial exposure, which presumably disrupts the normal protective colonic flora; (2) acquisition of a toxigenic *C. difficile* organism; and (3) host factors, specifically the ability to mount a serum IgG antibody response against toxin A that determines if CDAD or asymptomatic colonization will occur (Figure 1).[71,72] Two major virulence factors have been identified in *C. difficile* organisms—toxin A and toxin B—and virtually all organisms either possess both toxins or neither. The



C. difficile acquisition
C. difficile acquisition
Antimicrobial(s)
Asymptomatic C. difficile colonization
CDAD
Hospitalization
Acquisition of a toxigenic strain of C. difficile and failure to mount an anamnestic Toxin A antibody response results in CDAD.

Figure 1. Schematic of the hypothesis for the pathogenesis of *Clostridium difficile*-associated disease (CDAD).[71,72] Patients acquire *C. difficile* spores from contact with health care workers or the environment, but will not become ill with CDAD unless they acquire a toxigenic strain, and are exposed to antimicrobials that disrupt the normal protective flora and fail to raise an anamnestic serum IgG antibody response to toxin A. Patients who quickly develop a high antibody response will become colonized but remain asymptomatic.

importance of a third toxin, binary toxin, found in some strains including the recent epidemic toxinotype III strain, is unknown. Toxin A-negative and B-negative *C. difficile* organisms possessing binary toxin do not cause disease in hamsters, but culture supernatants produce a positive assay in rabbit ileal loops.[73,74] Nontoxigenic organisms are not considered capable of producing CDAD, but toxigenic strains appear to differ in their ability to produce CDAD, possibly on the basis of ability to produce toxins; however, in vitro production of toxin has correlated poorly with disease in the hamster model.[22,51,75,76]

Evidence for host factors in the pathogenesis of CDAD include the observation that asymptomatic colonization, including colonization with toxigenic and epidemic strains, is common and appears to be associated with significant protection against subsequent CDAD.[77] The immune response is a potentially important host factor and some indirect evidence supporting a role for immunity has been found in the pediatric population. Among children with chronic diarrhea, *C. difficile* is isolated more often among those with hypogammaglobulinemia than among those with normal immunoglobulin levels.[78] Moreover, children with chronic relapsing *C. difficile* colitis who had low levels of antitoxin A IgG showed both clinical and microbiological responses and increased levels of antitoxin A IgG following treatment with intravenous gamma globulin.[79] Patients with CDAD develop systemic and mucosal antibody responses to toxin A.[80,81] Failure of patients to raise their serum IgG antibody response promptly to toxin A when infected with a toxigenic strain of *C. difficile* has correlated with CDAD symptoms and with recurrence of CDAD.[71,82] In contrast, patients who raise their serum IgG antibody response to toxin A remain asymptomatic following acquisition of the organism, and those who raise their serum IgG antibody response to toxin A during treatment are less likely to have a recurrence.[71,82] Some investigators have found lower antitoxin A levels in patients with prolonged diarrhea and in those with relapsing CDAD than in patients with diarrhea of shorter duration and in those with CDAD limited to one episode.[83]

8. Patterns of Host Response

8.1. Clinical Features

Most patients with symptomatic *C. difficile* infection present with diarrhea. Fever is present in 28%, abdominal pain in 22%, and leukocytosis (>10,000/mm^3) in 50% of the patients.[17] A marked leukocytosis which frequently exceeds 20,000/mm^3 may indicate a bad prognosis, particularly if it continues to rise during treatment.[84] Very rarely, patients present with no prior diarrhea and have abdominal pain and tenderness, decreased bowel sounds, and an ileus pattern on abdominal X rays. Abdominal CT scans frequently reveal markedly thickened colonic mucosa and ascites in patients with ileus and severe or fulminant CDAD. Severe complications include toxic megacolon and colonic perforation, both of which are rare but life threatening. Rare cases of extraintestinal infection with *C. difficile* have been reported and include splenic abscess, bacteremia, osteomyelitis, cellulitis, and reactive arthritis.[85,86]

8.2. Diagnosis

The diagnostic definition of CDAD should include (1) diarrhea (variously defined as six watery stools in 36 hours, three or more unformed stools in 24 hours for 2 days, or eight unformed stools in 48 hours); (2) PMC visualized by endoscopy, or toxin A or B detected in stool, or stool culture positive for toxin-producing *C. difficile*; and (3) no other recognized etiology for diarrhea. In addition, a history of antimicrobial administration within the previous 8 weeks is present in nearly all patients, but is not included in the diagnostic definition to allow comparison of antimicrobial use as a risk factor. Endoscopy is the only means to diagnose PMC, but the sensitivity of endoscopy in patients with CDAD is only

51–55%, and the procedure is costly and invasive.[17,42] Most diagnoses of CDAD are made by stool laboratory testing; the cell cytotoxin test is most specific, but culture is the most sensitive. Most clinical laboratories in the United States test for toxin A or toxins A and B using an enzyme immunoassay method which is not as sensitive as the cell cytotoxin test or stool culture for *C. difficile*.

9. Control and Prevention

9.1. General Concepts

Efforts to control and prevent CDAD in institutions have been frustratingly difficult and remain a major area of needed research. Control measures have been of two types: those designed to prevent the patient from acquiring the organism and those designed to minimize risk of clinical illness if the organism is acquired. Barrier precautions are recommended to prevent transmission and include use of gloves by personnel, which has been shown to be effective in one hospital trial,[70] and isolation, cohorting, and hand washing, which are recommended but have not undergone rigorous clinical trials of efficacy. Alcohol hand rubs are ineffective in removing spores of *C. difficile,* therefore hand washing with soap is the preferred hand hygiene method. Efforts to reduce environmental contamination by disinfection and cleaning with sporicidal agents such as hypochlorite solution (1:10 diluted bleach) have demonstrated efficacy in reducing CDAD rates on a bone marrow transplant unit, reducing the CDAD rate from 8.6 to 3.3 cases per 1,000 discharges in one clinical trial.[87] Identification and removal of contaminated inanimate objects such as electronic rectal thermometers have been demonstrated to effectively reduce transmission.[69] Treatment of asymptomatic patients with metronidazole or vancomycin has been proposed as a means to prevent these patients from being a source of contamination of the environment and other patients, but metronidazole has been shown to be ineffective and vancomycin to be only transiently effective in reducing *C. difficile* in the stool.[88] Among the methods directed at reducing the risk of CDAD, the most effective has been control of antimicrobial usage, particularly clindamycin, which has been particularly effective in controlling outbreaks caused by clindamycin-resistant *C. difficile*.[59,89] Control of second and third generation cephalosporin use has also been associated with reduced CDAD rates.[90,91] Outbreak strains since 2000 in the United States, Canada, and Europe are resistant to newer fluoroquinolones, moxifloxacin, and gatifloxacin, and receipt of a fluoroquinolone antibiotic has been a risk factor for CDAD in hospitals experiencing outbreaks with this strain.[20] In one long-term care institution harboring the epidemic strain, CDAD rates decreased markedly when levofloxacin was substituted for gatifloxacin.[92]

9.2. Prophylaxis

Prophylactic treatment of patients receiving antimicrobials in order to prevent CDAD has been attempted in a clinical trial using a yeast, *Saccharomyces boulardii*, which significantly reduced antimicrobial-associated diarrhea, but did not reach statistical significance in reducing CDAD.[93] A review of the use of probiotics for prevention and treatment of CDAD concluded that there is insufficient evidence for the routine clinical use of probiotics to prevent or treat CDAD.[94]

9.3. Immunizations

No immunization against CDAD is currently available, but a vaccine is under development.

10. Unresolved Problems

10.1. Epidemiology

The major epidemiological question that is unresolved is the mechanism of *C. difficile* transmission in health care institutions. In addition, there is a marked need for simple, rapid, and inexpensive diagnostic tests that will increase the rapidity of patient diagnosis and thus reduce infection transmission. Much of traditional epidemiology is focused on clinical disease recognition and isolation and cohorting of the clinically ill. It is unclear what role asymptomatic patients play in the transmission process. If it were easier to identify these patients, their role in disease transmission could be better defined. Rapid, inexpensive, and sensitive organism typing methods are needed as a tool to better define the molecular epidemiology and transmission of *C. difficile.*

10.2. Control and Prevention

Traditional barrier methods other than wearing gloves have not been particularly effective in controlling *C. difficile* in hospitals. Efforts to more appropriately utilize antimicrobials will help to reduce undue risk to patients, but antimicrobial use in today's high-technology intensive care hospital environment is unavoidable and essential for treatment of some patients. Vaccines and colonization by nontoxigenic strains of *C. difficile* hold promise.[77] Efforts to better define the role of immunity could result in innovative vaccine

development. Prophylactic measures to prevent disruption or reconstitute the bowel flora should also be considered.

CHAPTER 14

Diphtheria

Melinda Wharton

1. Introduction

Diphtheria is an acute infectious and communicable disease caused by *Corynebacterium diphtheriae*. The organism infects primarily the respiratory tract, where it causes tonsillopharyngitis and/or laryngitis, classically with a pseudomembrane, and the skin, causing a variety of indolent lesions. If the infecting strain produces exotoxin, organ damage, especially myocarditis and neuritis, may ensue. The incidence of the disease has declined to low levels in most industrialized nations due to mass immunization with diphtheria toxoid. However, in the 1990s a diphtheria epidemic occurred throughout the former Soviet Union, resulting in more than 157,000 reported cases and 5,000 deaths. Thus, it is not safe to assume that diphtheria will remain a disease of the past.

2. Historical Background

Although possibly recognized as a clinical entity by Hippocrates (4th century BC), Aretaeus of Cappadocia (2nd century AD) gave the first clear description of respiratory diphtheria, which he called Egyptian or Syrian ulcers. Aëtius of Ameda (6th century AD) gave the first description of epidemic diphtheria and mentioned palatal paralysis as a sequel. Repeated epidemics of diphtheria (which was called *garrotillo* in Spain) were reported in Western Europe from the 15th century and in the New England states of the United States from the 16th century. Samuel Bard of New York (1771) described laryngeal diphtheria in a work entitled *Angina Suffocativa*. Bretonneau (1826) gave the disease its present name, using the Greek word for tanned skin or leather, after the tough pseudomembrane, and differentiated it from other diseases of the upper respiratory tract. Klebs (1883) identified the diphtheria bacillus by microscopic examination of diphtheritic membranes and associated it with the disease, and Loeffler (1884) first cultivated the organism on artificial media, established the causal relationship of the diphtheria bacillus by producing the disease in guinea pigs, and identified asymptomatic infections (carriers) among healthy children. Loeffler observed that the organism appeared to remain localized in the membrane without systemic invasion and hypothesized that damage to cardiac and nervous tissues was due to absorption of toxins elaborated by the organism. This was confirmed by Roux and Yersin (1888), who demonstrated that sterile filtrates of diphtheria cultures would kill guinea pigs and produce lesions identical to those that occurred after injection of the organism. Von Behring (1890–1893) showed that serum obtained from animals immunized against diphtheria toxin could be used for the prevention and treatment of the disease. For this work he received the first Nobel Prize in Medicine in 1901. Theobald Smith (1907) began the development of active immunization against diphtheria by reporting that durable immunity to the disease could be induced in guinea pigs by the injection of mixtures of diphtheria toxin and antitoxin. Schick (1913) introduced the skin test for susceptibility that bears his name. Ramon (1923) inactivated diphtheria toxin using formalin and heat, producing diphtheria "toxoid," which was non-toxic but able to induce protective antibodies. Vaccination with diphtheria toxoid was gradually introduced after 1930 and became universal in industrialized countries by the late 1940s. Freeman (1951),[1] Groman (1953),[2] and others demonstrated that avirulent *C. diphtheriae* were rendered toxigenic when infected by a specific β-phage. Pappenheimer, Gill, and associates (1952–1973)

Melinda Wharton • National Immunization Program, Centers for Disease Control and Prevention, Atlanta, Georgia 30333, USA.

have clarified the molecular mechanisms involved in the pathogenesis of the disease.[3] The evolution of knowledge about diphtheria has been important in the history of medicine, significantly influencing the development of bacteriology, immunology, pathology, epidemiology, and public health.[4]

3. Methodology

3.1. Sources of Morbidity and Mortality Data

In the United States, reporting of cases of respiratory diphtheria by health care providers is mandated in all states. In some states, hospitals and other health care facilities are also required to report cases. Cases are reported electronically to the National Notifiable Disease Surveillance System (NNDSS) and published in the weekly *Morbidity and Mortality Weekly Report* (MMWR) and annually in the MMWR Summary of Notifiable Diseases. Because diphtheria is now rare, cases reported to the NNDSS are verified before publication. If the diagnosis of diphtheria is suspected, diphtheria antitoxin (DAT) for treatment of the patient is obtained from the Centers for Disease Control and Prevention (CDC), which provides DAT within the United States under an Investigational New Drug protocol.[5] A CDC epidemiologist follows the case to collect supplemental data and to determine whether it meets criteria for reporting. It is thus likely that reporting of recognized diphtheria cases and deaths is nearly complete. The CDC maintains a database with supplemental data on diphtheria cases including vaccination status, complications, and outcome and publishes periodic summaries of the epidemiology of diphtheria in the United States.[6–9]

Since 1980, cutaneous diphtheria has not been a reportable disease in the United States. However, state public health laboratories are requested to send all *C. diphtheriae* isolates from any body site, whether toxigenic or nontoxigenic, to the CDC laboratory for confirmation.[10]

Worldwide, countries report annual numbers of diphtheria cases to their World Health Organization (WHO) regional office, and these data are collated by WHO headquarters in Geneva. The timeliness and completeness of such reporting are variable.

3.2. Surveys

Population immunity to diphtheria is evaluated by measuring serum levels of diphtheria antitoxin in a sample of the population. The National Health and Nutrition Examination Survey (NHANES) is a population-based survey of a representative sample of the US civilian noninstitutionalized population, conducted by the National Center for Health Statistics. Diphtheria antitoxin levels were determined by in vitro neutralization assay of approximately 18,000 sera collected during NHANES III (1988–1994). Sixty percent of Americans 6 years of age and older had fully protective levels of diphtheria antitoxin ($\geq$0.10 International Unit [IU]/mL), but only 30% of those 60 years of age and older had protective levels.[11]

Serologic studies were undertaken in many countries following the outbreak of diphtheria in the former Soviet Union. The level of population immunity observed varied by when diphtheria immunization was introduced and when high coverage was achieved, as well as by the specific immunization schedule used. For example, diphtheria gradually came under control in West Germany during the 1950s and in East Germany by the early 1960s. Analysis of serum specimens collected in Germany during the late 1990s demonstrated that a lower proportion of adults 40–49 years of age had protective levels of diphtheria antitoxin than younger age groups—who were more likely to have received childhood immunization—and older persons, who were more likely to have contracted diphtheria in childhood. In contrast, in Finland and the Netherlands, the age groups with the highest levels of susceptibility were the elderly.[12] A similar patter is seen in England and Wales, where 29% of adults 60 years of age and older had diphtheria antitoxin levels of 0.01 IU/mL or greater; however, the proportion with fully protective titers was much lower.[13] In Australia, approximately one-third of adults 50 years and older had fully protective titers of diphtheria antitoxin, and more than 50% had titers of 0.01 IU/mL or greater.[14]

No carrier surveys have been performed in the United States for many years; in the United States, laboratories do not routinely screen pharyngeal specimens for *C. diphtheriae*, although this is still recommended in some countries such as the United Kingdom.[15]

3.3. Laboratory Diagnosis

3.3.1. Isolation and Identification of the Organism. *Corynebacterium diphtheriae* is an aerobic, non-motile, unencapsulated, pleomorphic, gram-positive bacillus. The organism has four biotypes—*mitis, gravis*, *intermedius* and *belfanti*—distinguished by varying biochemical and hemolytic reactions.

There are several excellent reviews of the recommended procedures for the isolation and identification of *C. diphtheriae*.[16–20] If the diagnosis of diphtheria is suspected, the laboratory should be informed, since on

the traditional blood agar used for culture of respiratory specimens the organism may be overgrown or confused with nonpathogenic coryneform bacteria ("diphtheroids"). In respiratory diphtheria, material should be obtained for culture using a cotton- or polyester-tipped swab from both the posterior nasopharynx and the posterior oropharynx. If possible, specimens should be taken from beneath the margin of the membrane if one is present. If transport to the laboratory will be completed promptly, dry swabs are satisfactory; for periods of up to 24 hr, a general transport medium (e.g., Stuart or Amies) should be used; for longer periods, transport in silica gel sachets is recommended.[21] In stained smears, the organisms are club shaped (Greek *korynee*, club) and may form characteristic "Chinese letter" patterns. However, diagnosis on the basis of direct smears is not reliable and should instead rely on culture and confirmatory tests.

For primary isolation, swabs should be inoculated onto both blood agar and a tellurite-containing medium, which selectively inhibits the growth of other organisms. On tellurite media, *C. diphtheriae* typically forms brownish-black or grayish-black colonies within 18–48 hr, but other organisms may also produce similar-appearing colonies. Smears of suspicious colonies can be examined under Gram's or methylene blue stain to give a presumptive report. Colonies are taken to set up toxigenicity testing and also inoculated onto Pai or Loeffler's slants for biochemical testing, in which the pattern of metabolism of sugars, nitrate, and urea is used to confirm the species and determine biotype. Several commercial identification systems are available.

Historically toxigenicity testing was carried out in vivo by cutaneous inoculation of guinea pigs or rabbits,[22] but this is now rarely performed. More common is in vitro testing using a modified version of the immunodiffusion test originally developed by Elek.[23] In this test, an antitoxin-impregnated strip is laid along the surface of a culture plate containing Elek's medium; test and control cultures are streaked perpendicularly across the strip. Toxigenic organisms are identified by lines of toxin–antitoxin precipitate in the medium. Results are available within 24–48 hr in experienced laboratories. Other modifications to the Elek test have more recently been described which may allow detection of a positive result at 24 hr or less.[24] Many reference laboratories now perform a polymerase chain reaction (PCR) assay for detection of the diphtheria toxin structural gene (*tox*).[25–27] PCR has been found to be sensitive and specific for screening primary isolates, although false-positive toxigenicity tests may occur in isolates with nonfunctional *tox* genes. For this reason, it is recommended that PCR be used in conjunction with the Elek assay, in order to confirm the production of diphtheria toxin.[28] Cysteinase and pyrazinamidase are useful screening tests to distinguish *C. diphtheriae* and the other two potentially toxin-producing species, *C. ulcerans* (which may cause a diphtheria-like illness) and *C. pseudotuberculosis*, from other species of the genus *Corynebacterium*.[18]

A number of molecular techniques, including ribotyping, pulsed-field gel electrophoresis, multilocus enzyme electrophoresis, and the random amplified polymorphic DNA (RAPD) assay, have been used in recent years to describe the molecular epidemiology of diphtheria outbreaks.[29–33] Ribotyping has been most extensively applied and standard nomenclature has been developed.[34] These techniques have been used extensively to characterize isolates from the recent epidemic in the countries of the former Soviet Union[30,35–38] as well as to demonstrate long-term persistence of circulation of *C. diphtheriae* in two communities in the United States and Canada.[39,40]

3.3.2. Serological and Immunologic Diagnostic Methods. Immunity to diphtheria presumably involves both humoral and cell-mediated immunity to multiple antigens of *C. diphtheriae*.[41] In practice, however, only the level of diphtheria antitoxin (antibodies to diphtheria toxin) is measured. Based on the level of antitoxin associated with Schick test conversion and studies of levels of circulating antitoxin in patients at the time of hospitalization with clinical diphtheria,[42–44] it is generally agreed that persons with levels below 0.01 IU/ml have no protection against diphtheria and increasing levels above that correspond to increasing levels of protection. Some authorities differentiate 0.01 IU/ml as the minimum protective level and state that levels from 0.01 to 0.1 IU/ml confer relative or partial protection, levels of $\geq$0.1 IU/ml provide more reliable protection, and levels $\geq$1.0 IU/ml confer long-term protection.[18,45] However, no level of antitoxin provides absolute protection against clinical diphtheria.[42]

Formerly, the Schick test was widely used to determine population immunity to diphtheria.[46,47] The test is performed by subcutaneous injection of a small standardized quantity of diphtheria toxin intradermally in one arm, with a control injection of diphtheria toxoid in the opposite arm. The result is determined after 24–48 hr and again 5–7 days after inoculation. A positive erythematous skin reaction to toxin but not to toxoid indicates susceptibility. The antitoxin level at which the Schick test conversion occurs is around 0.30 IU/ml.[48]

Several assays for determination of diphtheria antitoxin level in serum have been developed. The "gold standard" tests are neutralization assays: in vivo tests performed in animals and the more convenient but equally accurate in vitro cell culture methods.[49] The enzyme-linked immunosorbent assay (ELISA) is simpler and/or less costly than the neutralization tests; while the ELISA is acceptable for population

surveys, it lacks sensitivity compared to neutralization tests for antitoxin levels below 0.1 IU/ml, and therefore is of limited usefulness for assessment of the individual patient.[50] The major role of serological tests is in periodic surveys to determine levels of population immunity to diphtheria. Individual immunity is assessed in two main settings: most commonly in modern practice, to determine antibody response to diphtheria toxoid in vaccine studies or as part of an immunologic assessment, and in the setting of suspected diphtheria, to determine the patient's antitoxin level before therapeutic antitoxin is administered. If this level is later found to be high, the diagnosis of diphtheria is less likely; a low level, while consistent with possible diphtheria, does not prove the diagnosis. Antibody response to diphtheria infection is unreliable for diagnosis, since many patients do not mount a significant antibody response, and available assays in the United States do not distinguish between human antibodies and equine antitoxin used for treatment.

4. Biological Characteristics of the Organism

Humans are apparently the only natural host and reservoir of *C. diphtheriae*. Toxigenic organisms have only been isolated from man and from certain domestic animals closely associated with man, such as horses, cows, sheep, and dogs. It is believed that this represents colonization of such animals due to human contact, rather than representing a source of infection for humans. Experimental infections can be induced in a variety of animals. *C. diphtheriae* is moderately resistant to physical factors such as drying; organisms can be cultured from the environment of patients[50] and may survive in dust for up to several weeks.[51]

The major virulence factor produced by *C. diphtheriae* is diphtheria toxin. Both toxin-producing (toxigenic) and non-toxin-producing (nontoxigenic) strains exist in nature. Expression of toxin depends on infection of the *C. diphtheriae* strain by a number of lysogenic corynephages, which carry the toxin gene (*tox*). Integration of phage DNA into the bacterium allows expression of toxin, which is facilitated by low iron conditions. Nontoxigenic strains can be converted to toxigenic ones in vitro by infection with a tox^+ phage. In addition, there have been reports of carriers simultaneously infected with toxigenic and nontoxigenic strains that appear to be identical by phage typing and DNA restriction analysis, differing only in the presence of a tox^+ β-phage.[52] This suggests that conversion of nontoxigenic *C. diphtheriae* strains to toxigenicity may occur in vivo in the human pharynx. If so, the *tox* gene could be introduced into a community following the arrival of a toxigenic strain by direct spread of that strain, but also indirectly by release of the tox^+ phage, which then may spread within the resident population of circulating nontoxigenic strains.[52]

Additional virulence factors that have been described include two cell wall components: K antigens, which appear to be important in the establishment of infection, and a glycolipid named "cord factor," which disrupts mitochondrial function.

Nontoxigenic *C. diphtheriae* may cause pharyngitis without a membrane[50,53] and a localized diphtheria-like membranous tonsillopharyngitis.[44] Although such patients do not suffer toxin-induced complications such as myocarditis and neuritis, their illness may sometimes be severe and occasional deaths are reported.[8,44] Nontoxigenic *C. diphtheriae* may cause invasive disease, including endocarditis and arthritis. Such patients usually, but not invariably, have underlying risk factors.[54–59]

Resistance of *C. diphtheriae* to penicillin has not been demonstrated,[60–64] but organisms resistant to erythromycin, clindamycin, tetracycline, and rifampin have been described.[61,65–68] There is one report of erythromycin resistance in four strains isolated from respiratory carriers after a 7-day course of erythromycin.[69] The other reported erythromycin-resistant isolates have been cutaneous isolates, with plasmid-mediated resistance and associated with previous receipt of erythromycin by the patient or with widespread use of this antibiotic for treatment of pyoderma in the community.[70] More recently intermediate resistance to erythromycin has been reported in some isolates from epidemic areas in South Asia and isolates from sporadic cases in Australia.[19] Rifampin resistance was documented in isolates from two members of a single family in Estonia.[61]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

In industrialized nations, until the 1920s–1930s, up to 10% of children in urban areas developed clinical diphtheria. Asymptomatic infection was even more common, and by 15 years of age, 70–80% of children in cities such as New York, Baltimore, and London were immune to diphtheria.[47,71,72] Diphtheria incidence in the United States (but not in England and Wales) declined before the advent of widespread diphtheria vaccination, probably because transmission was reduced as improving social conditions resulted in reduced crowding and improved hygiene. The increasing implementation of diphtheria toxoid vaccination from the late 1920s and its universal use from the late 1940s led to a steady decline in diphtheria incidence.

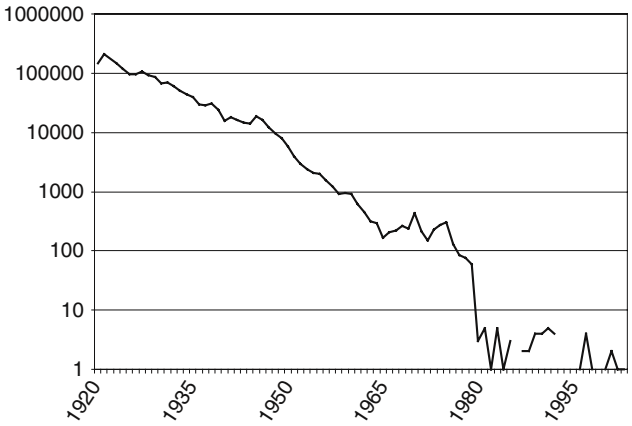

Figure 1. Diphtheria, United States, 1920–2004: Reported cases by year. No cases of respiratory disease due to *C. diphtheriae* were reported in 1986, 1993, 1995, 1999, and 2004–2005.

In the United States, the highest number of diphtheria cases reported since national reporting began in 1920 was 206,939 in 1921 (Figure 1), an incidence rate of 191 per 100,000 population. The same year, 15,520 deaths from diphtheria were reported (mortality rate 14.3 per 100,000 population, case fatality ratio 7.5%). Over subsequent decades, diphtheria incidence and mortality rates progressively decreased, while the case fatality rate remained little changed.[8] Lower case fatality ratios during the 1970s reflected the increased proportion of cutaneous diphtheria cases, which are rarely fatal, reported during that period. The last major outbreak of diphtheria in the United States occurred in King County, Washington, from 1972 to 1982.[70] Of 1,100 cases identified during the outbreak, 947 (86%) were cutaneous infections. From 1980 to 2005, a total of 51 cases of diphtheria due to infection with *C. diphtheriae* were reported in the United States, of which 20 (39%) were confirmed by culture (Figure 2). An additional three cases of respiratory disease due to infection with toxigenic strains of *C. ulcerans* also were reported. Although diphtheria is a rare disease in the United States, endemic foci have been documented in communities in both the United States and Canada.[39,40,73] In less developed nations, diphtheria vaccination was introduced with the expanded program on immunization (EPI) in the late 1970s. Before this, it was estimated that close to 1 million cases of diphtheria occurred annually in developing countries, with 50,000–60,000 deaths.[74] Until the 1990s, reported diphtheria was decreasing in all regions, and eradication of diphtheria was considered possible.[75] However, during the 1990s, epidemic diphtheria returned to the new independent states of the former Soviet Union. As few as 198 cases (0.08 per 100,000 population) were reported in the entire Soviet Union in 1976; in 1989, 839 cases. The epidemic began in Russia in 1990, spread to Ukraine in 1991, and in 1993–1995 spread to the other new independent states. At the height of the epidemic, in 1994–1995, almost 100,000 cases were reported in the new independent states. With aggressive implementation of immunization programs aimed at both children and adults, the outbreak came under control in the late 1990s.[76] A hypothesis to explain why a dramatic drop in the incidence of diphtheria has followed use of a vaccine that induces immunity only to the *tox* gene of *C. diphtheriae* has been advanced by Pappenheimer.[3] The *tox* gene is not essential to the growth of the organism, but likely confers upon it a selective advantage in nonimmune populations. The toxin, by producing tissue necrosis and a site for greater replication of the bacterium in diphtheria cases, facilitates its spread to other susceptible persons. However, in an immune population, infection with toxigenic *C. diphtheriae* does not lead to clinical disease, and this selective advantage is lost, which leads to a reduction in the circulation of toxigenic *C. diphtheriae*. Pappenheimer cites data from Romania in support of this theory. Routine diphtheria immunization began in Romania in 1958, and within several years, the percentage of Schick-negative (immune) individuals in the population had increased from 60 to 97%. The incidence of diphtheria fell rapidly to very low levels. Analysis of *C. diphtheriae* isolates from carriers revealed that, lagging behind the fall in diphtheria incidence, the proportion of strains that were toxigenic fell from 87% in 1958 to only 4% in 1972. The low incidence of diphtheria observed in countries that have maintained high immunization coverage among children is consistent with Pappenheimer's hypothesis, but data on the prevalence of carriage with either toxigenic or nontoxigenic *C. diphtheriae* are limited.

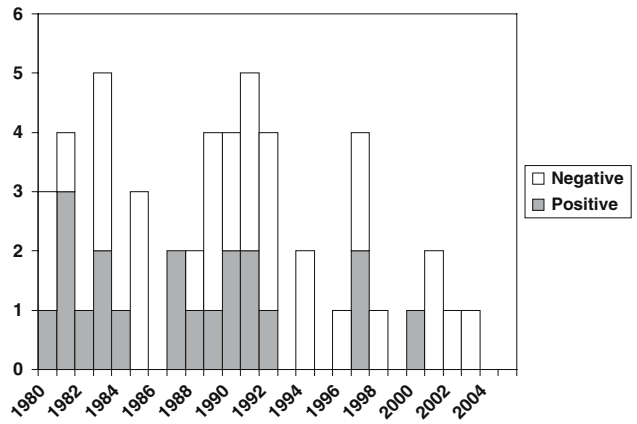

Figure 2. Respiratory diphtheria, United States, 1980–2005. Cases by year and culture status. Data for 1980–1995 from ref. 9.

5.2. Epidemic Behavior and Contagiousness

From at least the 15th century in Europe, diphtheria occurred in epidemics of varying virulence. During some periods there appeared to be a 12- or 15-year periodicity to these outbreaks, but there were also intervals of several decades with little reported diphtheria. Diphtheria incidence increased in the latter part of the 19th century in Europe and the United States, with high case fatality rates.[77] There were significant increases in diphtheria incidence during World War II in many countries, which has been attributed to dissemination of *C. diphtheriae* by military personnel returning from desert or tropical areas.[78,79] In the vaccine era, outbreaks, usually quite limited in geographic extent, have continued to occur in industrialized countries, but with decreasing frequency. However, the epidemic which occurred in the former Soviet Union represented a significant reversal in this trend.

Both asymptomatic carriers and clinical cases are important in the spread of diphtheria. In household settings, up to 27% of close contacts of cases may be found to be infected.[80] Transmission from cases is more efficient than from asymptomatic carriers, presumably because of the greater number of infecting organisms (and perhaps certain features of the infecting organism). Secondary cases are at least 10 times more common after household exposure to cases compared to household exposure to carriers.[81] Although carriers are less infectious than cases, in diphtheria endemic areas, carrier prevalence is many times higher than the prevalence of cases; therefore, carriers have a greater role in transmission. This problem is exemplified by noting that during the first decades of the 20th century, 2–5% of schoolchildren in urban areas were carriers of toxigenic *C. diphtheriae*.[72,81]

5.3. Geographic Distribution

In the prevaccine era, diphtheria had a worldwide distribution. In temperate regions, respiratory diphtheria predominated, with cutaneous diphtheria being relatively uncommon. By contrast, in many (but not all) tropical and desert regions, cutaneous diphtheria was the usual form of the disease, with little or no respiratory diphtheria reported despite moderate rates of pharyngeal carriage of *C. diphtheriae*. In these countries, intense skin transmission appears to occur in the first few years of life, resulting in development of immunity to diphtheria toxin.[82–84]

Since the 1980s, a state of near elimination of toxigenic *C. diphtheriae* has existed in many industrialized countries. However, with the extent and rapidity of travel today, there is a continuing potential for outbreaks in such countries following importation of toxigenic strains from countries where diphtheria is still occurring.[85,86,87] Such an event was suspected as the reason for a series of outbreaks, with 33 cases of respiratory diphtheria, that occurred in Sweden in the mid-1980s, after the absence of indigenous diphtheria for 20 years.[31,32] Additionally, foci of endemic transmission of *C. diphtheriae* have been identified in both the United States and Canada.[39,40] Thus, clinicians, public health authorities, and laboratorians all must remain vigilant, in spite of low incidence now seen in many countries.

5.4. Temporal Distribution

Diphtheria has a marked seasonal variation in incidence in temperate countries. Incidence peaks in the autumn and early winter and is at its lowest in late spring and early summer.[88]

5.5. Age

Until the 1970s, respiratory diphtheria was a disease of children. The highest attack rates were among preschool children and schoolchildren aged 5–9 years. Eighty to ninety percent of cases were among children aged less than 15 years.[72] However, in the vaccine era, there has been a shift in the age distribution toward adults.[89] In the United States from 1980 to 1995, 27 (66%) of the 41 reported diphtheria cases were among persons aged over 20 years.[9] In the recent outbreak in the former Soviet Union, a majority of reported cases were among adolescents and adults, although the proportion of cases by age group varied among the countries.[76] This change in age distribution is explained by the fact that children are mostly protected by immunization, whereas many adults are now susceptible, because exposure to toxigenic *C. diphtheriae* has become rare and vaccine-induced immunity wanes over time unless periodic booster doses of diphtheria toxoid are given. Susceptibility may be particularly high among those cohorts who were children during the early years of diphtheria immunization program, who may have grown up during a period of decreased diphtheria incidence but not all children were vaccinated. This presumably accounts for the severity of the disease and high case fatality rate for adults 30–50 years of age that was observed in the former Soviet Union.[76]

5.6. Sex

There does not appear to be a particular susceptibility of either gender to clinical diphtheria. If gender-specific differences in incidence occur, they probably reflect differences in levels of exposure of *C. diphtheriae*. During the outbreak

in the former Soviet Union in the 1990s, women had higher incidence rates than did men in those areas where the sex distribution of cases was assessed.[76] In Ukraine, disease incidence was similar between boys and girls <10 years of age, but among older adolescent girls and women, incidence rates were higher than those observed among males.[90] In Kazakhstan, 63% of adult case-patients were female,[91] and in Moldova, incidence rates were 2- to 3-fold higher among women than among men.[92] These differences are thought to reflect greater contact by older adolescent and adult females with children, compared to males.

5.7. Race

In the United States during the period 1959–1970, the incidence rate among Native Americans was 3 times higher than persons of black race and 20 times higher than persons of white race.[7] From 1971 to 1981, incidence rates of respiratory diphtheria were approximately equal in whites and blacks, but rates in Native Americans were 100 times higher.[6] A strikingly higher incidence of diphtheria, particularly of the skin and ear, among Native American populations has also been noted in Canada.[93] Endemic circulation has been documented in a Native American community in South Dakota.[73] A higher incidence of diphtheria, in comparison to whites, has also been reported in Australian aborigines.[94] These racial differences likely represent mostly differences in living conditions (e.g., increased contact rates and reduced hygiene) that promote transmission of diphtheria, particularly in its cutaneous form.

5.8. Occupation

Medical workers exposed to diphtheria in the prevaccine era were reported as having developed higher rates of carriage of the organism compared to the general population.[72] Although cases of clinical diphtheria did occur among medical personnel, frequently the result was asymptomatic infection, since high levels of immunity were maintained by continuing exposure to diphtheria patients. More recent studies of hospital staff contacts of diphtheria cases indicate a low risk of acquisition of the organism.[80]

Diphtheria outbreaks have frequently been reported among military personnel, particularly when deployed in tropical or desert settings, and returning soldiers can import diphtheria into civilian populations.[83,95–97] The Soviet military appears to have played a role in the recent epidemic of diphtheria in the former Soviet Union.[98,99] Military personnel are at increased risk of diphtheria because of crowded living conditions and, especially in combat situations, poor hygiene and frequent occurrence of skin lesions, which can become secondarily infected with *C. diphtheriae*.

5.9. Occurrence in Different Settings

The most recent outbreaks in the United States and Western Europe have characteristically involved innercity, indigent, homeless, and/or alcoholic persons (so-called "skid road" inhabitants).[31,43,70] Such persons were also said to experience an increased risk of diphtheria in the recent outbreak in the former Soviet Union.

Institutional outbreaks have occurred in mental hospitals (where the clinical diagnosis of diphtheria may be delayed), day care centers, and schools.[80,97,100–102] Schools and preschool institutions have traditionally been an important setting for transmission among children.[81,100,103–104]

5.10. Socioeconomic Factors

Low socioeconomic status is a risk marker for diphtheria, to the extent that it is associated with crowded living conditions and reduced hygiene and with reduced immunization levels.

6. Mechanism and Routes of Transmission

The organism is carried in the nose and throat[105] and appears to have a particular predilection for tonsillar tissue.[106,107] It also readily infects cutaneous lesions. Transmission occurs in close-contact settings via respiratory droplets or by direct contact with respiratory secretions or skin lesions. The organism survives on clothes and dust in the environment of cases, and fomite transmission via items such as clothes and towels may be important, particularly in settings of crowding and poor hygiene.[50,108] Compared to respiratory carriers, persons with skin lesions infected with *C. diphtheriae* (which frequently are unrecognized) apparently contaminate the environment with the bacterium and transmit it more efficiently to both the skin and respiratory tract of household and school contacts.[50,109,110] However, certain persons with nasopharyngeal infection—both cases and carriers—have been described as "spreaders" because of their apparently efficient dissemination of the organism. *C. diphtheriae* can be readily cultured from the upper lip, hands, and clothes of such individuals.[108] Foodborne transmission, most often by infected milk or milk products, has been occasionally implicated.[45,111,112]

7. Pathogenesis and Immunity

In classical respiratory diphtheria, *C. diphtheriae* colonizes the mucosal surface of the nasopharynx and multiplies locally without bloodstream invasion. The incubation period is from 1 to 7 days (usually 2–5 days). Released toxin causes local tissue necrosis and tough, adherent pseudomembrane forms, composed of a mixture of fibrin, dead cells, and bacteria. The membrane usually begins on the tonsils or posterior pharynx. In more severe cases it spreads, extending progressively over the pharyngeal wall, fauces, soft palate, and into the larynx (and on occasions further into the trachea and bronchi), resulting in respiratory obstruction. Toxin entering the bloodstream causes damage at distant sites, particularly the heart (myocarditis), nerves (demyelination), and kidney (tubular necrosis).

Primary infection of the skin may occur, which classically results in a "punched out" ulcer, often with a grayish membrane. However, more frequently *C. diphtheriae* appears to secondarily infect preexisting skin lesions.

Diphtheria toxin, a two subunit protein with a molecular weight of 61,000 kDa, is an extremely potent inhibitor of protein synthesis, with an estimated human lethal dose of 0.1 μg/kg body weight. The B subunit attaches to the cell surface. The A subunit enters the cell and, by ADP ribosylation, inactivates elongation factor 2, which is an essential factor in the transfer of amino acids to the nascent polypeptide chain.[3,113] The extent of toxin absorption varies with the site of infection, being much less from skin or nose than from the nasopharynx.

Immunity to clinical diphtheria appears largely to depend on the level of diphtheria antitoxin in the serum at the time of onset of illness (Section 3.2.2). Antibodies to fragment B of diphtheria toxin are able to neutralize the effect of toxin and protect against disease. Diphtheria antitoxin is predominantly IgG antibody.[114] It is transmitted transplacentally, providing protection to infants during the first 6 months of life.

Stimulation of antitoxin production occurs with either asymptomatic infection or disease, in addition to immunization with diphtheria toxoid. Following recovery from clinical diphtheria, development of protective immunity is not reliable[115] and vaccination is recommended in convalescence. The possession of protective levels of antibody does not prevent carriage of *C. diphtheriae* nor does it appear to affect the duration of carriage. On the contrary, identified carriers may have relatively high levels of antitoxin.[43]

Waning of the diphtheria antitoxin level occurs over time, following either natural infection or artificial immunization. Periodic booster doses of diphtheria toxoid are recommended to maintain protective levels of antitoxin. Although a boost in antitoxin levels may occur following the onset of disease in individuals who have been previously immunologically primed but whose antitoxin concentration has fallen below the protective level, in many cases the production of diphtheria toxin by the infecting organism is so overwhelming that the antitoxin response is not swift enough to prevent complications or even death.

8. Patterns of Host Response

8.1. Clinical Features

8.1.1. Carrier State. Asymptomatic nasopharyngeal infection with *C. diphtheriae* occurs more frequently than clinical disease. The duration of carriage was studied by several investigators during the preantibiotic era, by examining the rate of disappearance of *C. diphtheriae* from the nasopharynx of either convalescent cases or identified carriers. Hartley and Martin[106] followed 457 cases and found that 49, 74, and 87%, respectively, were culture-negative by 15, 30, and 45 days after illness onset. Weaver[116] studied the rate of disappearance of *C. diphtheriae* among 500 cases. After the first week, approximately half of the cases that began the week culture-positive became culture-negative during the following 7 days. By 3 weeks after onset, 71% had become culture-negative; by 4 weeks, 83%; and by 8 weeks, 99%. Weaver also studied the rate of disappearance of *C. diphtheriae* in 52 carriers: by 2 weeks after identification, 55.8% had become culture-negative and by 4 weeks, 80.8%. Two (4%) remained positive after 75 days. Differences between the results of these studies probably largely reflect the greater opportunity for reinfection of Hartley and Martin's patients. Both authors describe the association of chronic carriage with large, irregularly shaped tonsils and the value of tonsillectomy in eradicating carriage. However, this should not be necessary with the present availability of effective antibiotics.

8.1.2. Respiratory Diphtheria. Infection limited to the anterior nares manifests as chronic serosanguinous or seropurulent discharge, without fever or significant toxicity. A whitish membrane may be observed on the septum. Such patients may readily spread diphtheria. The faucial (pharyngeal) form is the most common. The illness begins insidiously with a sore throat, malaise, and mild to moderate fever. There is an initial mild pharyngeal erythema, usually followed by progressive formation of a whitish tonsilar exudate, which over 24–48 hr changes into a gray adherent membrane, which is tightly adherent and bleeds upon attempted removal. In more severe cases, the patient appears toxic and the membrane is more extensive. Gross

enlargement of cervical lymph nodes and surrounding tissue edema may occur, resulting in the so-called "bull neck." Laryngeal involvement, which may occur on its own or as a result of membrane extension from the nasopharynx, presents with hoarseness, stridor, and dyspnea. Intubation or tracheostomy may be required.

The likelihood of toxic complications depends on the severity of disease at presentation and the interval between disease onset and administration of therapeutic antitoxin. Myocarditis typically occurs between 1 and 2 weeks after the onset of respiratory symptoms. Neural impairment occurs in 10–20% of patients. In severe cases, palatal and/or pharyngeal paralysis may occur during the acute phase. Cranial nerve involvement may develop after the first week. Peripheral neuritis, symmetrical and predominantly motor, occurs from 2 to 12 weeks after disease onset. Motor deficit may range from minor proximal weakness to complete paralysis. Although slow (several months), recovery of neurological function is usually complete. In fulminant, sometimes called hypertoxic, diphtheria, toxic circulatory collapse with hemorrhagic features occurs. More severe disease occurs in the very young and the elderly and in unimmunized persons.

8.1.3. Cutaneous Diphtheria. Classical cutaneous lesions are indolent deep punched out ulcers, which may have a grayish-white membrane. More commonly, however, *C. diphtheriae* appears as a secondary infecting agent of a variety of dermatoses such as traumatic lesions, pyoderma, or chronic dermatitis, such as stasis dermatitis.[70,109] There is frequently coinfection with *Streptococcus pyogenes* and/or *Staphylococcus aureus*. Recognized toxin-induced diphtheria complications are usually stated to be uncommon, which is said to be because toxin absorption from the skin is much less than from the nasopharynx. However, toxin-induced neuritis and myocarditis were noted following cutaneous diphtheria among soldiers during World War II.[83,95]

8.1.4. Other Sites. The organism may uncommonly infect other sites, including the eye, genitalia, and ear.

8.1.5. Invasive Disease. Uncommonly, *C. diphtheriae*, both toxigenic and nontoxigenic, may cause invasive disease, including endocarditis, osteomyelitis, septic arthritis, and meningitis.[54–59] Frequently, but not always, these patients have predisposing factors such as a prosthetic cardiac valve or underlying immunosuppression.

8.2. Diagnosis

The decision to initiate therapy should be made on clinical grounds, since delay in treatment is associated with worse outcomes, owing to the fact that antitoxin can only neutralize toxin that has not already bound to cells. A high index of suspicion is required. Cultures should be taken from beneath the membrane, from the nasopharynx, and from any suspicious skin lesions. Because special media are required, the microbiology laboratory should be alerted to the concern about diphtheria. Cultures may be negative if the patient received previous antibiotics. The diagnosis of diphtheria is more likely if the patient is unimmunized or has not received recommended booster immunizations; if there is a history of contact with a known diphtheria case; if there is a history of recent travel to a region with endemic diphtheria or of contact with a recent immigrant from such an area; if the patient belongs to a population group that has had a higher risk of diphtheria in the past, such as homeless persons; and if the pretreatment antitoxin titer is <0.01 IU/ml.

The differential diagnosis of respiratory diphtheria includes bacterial (streptococcal, *Arcanobacterium hemolyticum*[117]) and viral tonsillopharyngitis, infectious mononucleosis, peritonsillar abscess, Vincent's angina, candidiasis, and acute epiglottitis. A nasal foreign body produces a unilateral nasal discharge that can mimic nasal diphtheria.

8.3. Treatment

The mainstay of therapy is equine diphtheria antitoxin, which should be administered as the diagnosis is reasonably suspected, without waiting for bacteriologic confirmation, in order to neutralize toxin before it binds to tissues. Antibiotic therapy (penicillin or erythromycin) is necessary to eliminate the organism, thereby halting further toxin production and preventing further transmission.

9. Control and Prevention

9.1. General Concepts

Recommendations for the prevention and control of diphtheria, including an algorithm to guide investigation and management, have been published by the CDC and by the WHO Regional Office for Europe.[80,118]

The important first step is recognition of suspected diphtheria by clinicians. Although most practicing clinicians have never seen a case of the disease, it is important that they remain aware of the possibility of diphtheria, particularly in a patient with a nasopharyngeal pseudomembrane. Identification of a suspected case should set in motion a series of activities. The health department should be notified so that the contact investigation can begin as soon as possible. The patient is placed in strict respiratory isolation, the laboratory notified of the suspicion of

diphtheria, and the appropriate cultures taken, if possible before antibiotics are begun. During and after treatment, isolation should be maintained until elimination of the organism is demonstrated by two negative cultures obtained at least 24 hr apart after completion of antimicrobial therapy. The patient should be immunized with diphtheria toxoid during convalescence.

Close contacts (which include household contacts and others spending at least several hours per week in close proximity to the patient, such as preschool and elementary school classmates), irrespective of vaccination status, should be (1) monitored for symptoms and signs of diphtheria for at least 7 days, (2) cultured from the nose and throat for *C. diphtheriae*, and (3) given antibiotic prophylaxis (Section 9.2). The immunization status of all close contacts should be assessed and diphtheria toxoid administered as indicated. Persons who have not previously received at least three doses of diphtheria toxoid should receive a dose of diphtheria toxoid and then further doses as necessary to complete the recommended schedule for age. The schedule can be completed irrespective of the interval between the previous doses. Persons who have received three or more previous doses of diphtheria toxoid should receive a further dose unless their last dose was received within the past 5 years. Contacts found to be carriers of *C. diphtheriae* should receive follow-up cultures a minimum of 2 weeks after completion of antibiotics, to ensure eradication of the organism.

9.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis

Although the effectiveness of antibiotic prophylaxis in preventing secondary cases among contacts is not proven, it is recommended[80,118,119] that all close contacts should receive antibiotic prophylaxis, after appropriate cultures have been taken. The importance of antibiotic treatment of carriers, in addition to immunization, in the control of diphtheria has been reinforced by experience during outbreaks in the United States.[100,103] If compliance is assured, a 7- to 10-day course of erythromycin (40 mg/kg per day for children and 1 g/day for adults, in divided doses) is recommended; if compliance is doubtful or if there is intolerance to erythromycin, a single intramuscular injection of benzathine penicillin (600,000 units for persons <6 years of age and 1.2 million units for persons ≥ 6 years of age) is preferred. Both clinical and laboratory data indicate that erythromycin may be more effective than penicillin.[120,121]

9.3. Immunization

Both theoretical data and the occurrence of outbreaks in even highly immunized communities[100,103,122,123] suggest that a high level of population immunity, perhaps greater than 85%, is necessary to prevent and to control outbreaks. This contrasts with earlier opinions (offered at a time when levels of natural immunity among adults were high) that diphtheria could be controlled if childhood immunization rates of 70% were achieved.[41] Now that natural exposure to toxigenic *C. diphtheriae* is rare, the necessary levels of immunity can only be realized by achieving childhood vaccination coverage of at least 95% and by achieving high coverage of adults with periodic booster doses of diphtheria toxoid. In 1999, 42% of adults 65 years of age and older reported receiving tetanus-containing vaccine (almost all of which likely included diphtheria toxoid, as adult formulation diphtheria and tetanus toxoids) within the previous 10 years. Coverage was higher among those aged 50–64 years (57%) and 18–49 years (66%).[124] Immunization with diphtheria toxoid is the mainstay of diphtheria prevention. Almost always, diphtheria toxoid is administered to children in vaccines in which it is combined with one or more other antigens (tetanus toxoid with or without pertussis vaccine [whole cell or acellular]: DT, DTP, and DTaP, respectively). Combination vaccines in which DTaP is additionally combined with inactivated polio vaccine (IPV) and hepatitis B vaccine, or IPV and *Haemophilus influenzae* type B conjugate vaccine are also available. Pediatric vaccines usually contain from 10 to 30 Lf (flocculation units) of diphtheria toxoid. For persons aged 7 years of age or older, adult formulation tetanus and diphtheria toxoids (Td) are used for both primary and booster immunization. The small "d" reflects a reduced amount of diphtheria toxoid (in many countries, approximately 2 Lf) in order to reduce adverse effects, particularly severe local reactions, experienced by some older individuals upon receipt of higher amounts of diphtheria toxoid.[125,126]

Three different vaccination schedules are shown in Table 1. Issues relating to the immunogenicity of different schedules have been reviewed elsewhere.[127] For both adults and children, three doses of diphtheria toxoid are required to raise antitoxin levels above the minimum protective level (0.01 IU/ml) in 100% of recipients.[127,128] In the absence of ongoing natural exposure to toxigenic *C. diphtheriae*, vaccine-induced immunity wanes over time.[129–133] Periodic diphtheria toxoid booster doses are therefore required to maintain immunity: in the United States, decennial boosters are recommended. In some tropical countries, ongoing exposure to cutaneous diphtheria may reduce the need for diphtheria toxoid boosters[127,134]; however, persons in

Table 1. Schedules for Diphtheria Vaccination Recommended in the United States, in the United Kingdom, and by the World Health Organization Expanded Program on Immunization

Dose	United States (ACIP, AAP)[141]		United Kingdom[142]		WHO, EPI[143]	
Primary						
1	2 months	DTaP	2 months	DTaP	6 weeks	DTP
2	4 months	DTaP	3 months	DTaP	10 weeks	DTP
3	6 months	DTaP	4 months	DTaP	16 weeks	DTP
4	12–18 months	DTaP	–		–	
Booster						
1	4–6 years	DTaP	3 years 4 months	DTaP or Tdap		
2	11–12 years	Tdap	–			
3	Every 10 years	Td				

Abbreviations: ACIP, Advisory Committee on Immunization Practices; AAP, American Academy of Pediatrics; WHO EPI, World Health Organization Expanded Program on Immunization.

low-endemic or non-endemic areas may require boosters at about 10-year intervals to maintain immunity.[135]

The most frequent adverse reaction to diphtheria toxoid is local pain at the site of inoculation, sometimes with associated redness and swelling and occasionally severe. Systemic reactions (fever and malaise) occur infrequently. Most such reactions are believed to represent hypersensitivity reactions to diphtheria toxoid or to associated impurities.[126] The assessment of adverse reactions is difficult because diphtheria toxoid is now almost always administered in combination with tetanus toxoid and other antigens; however, available data suggest that addition of diphtheria toxoid to tetanus toxoid results in more adverse reactions than are seen following tetanus toxoid alone.[135–138] Severe generalized anaphylactic reactions rarely have been reported.[139]

The effectiveness of diphtheria toxoid has never been measured in a controlled trial. Its value seemed obvious to early investigators, and the Schick test and serological methods provided measurable correlates of protection. However, studies comparing the incidence of diphtheria in vaccinated and unvaccinated individuals and case–control studies have provided estimates of effectiveness of 70–98%.[140] While immunization with diphtheria toxoid does not provide complete protection against clinical diphtheria, when disease occurs in fully vaccinated persons, it is generally milder and is rarely fatal.

10. Unresolved Problems

In this era of apparent near elimination of toxigenic *C. diphtheriae* from most developed nations, diphtheria is often considered a disease of the past, and therefore interest in research on this disease has waned, with the exception of ongoing molecular studies related to diphtheria toxin. Several issues related to nontoxigenic *C. diphtheriae* strains deserve study. The current epidemiology of nontoxigenic organisms is poorly understood. This information is potentially important, since the introduction, through an imported toxigenic strain, of a tox^+ phage into the resident pool of nontoxigenic organisms is more likely if they continue to circulate widely. Nontoxigenic organisms may cause local disease, at times severe; in addition, severe local disease due to toxigenic strains may occasionally occur in persons with high levels of diphtheria antitoxin. A better understanding of the pathogenesis of disease caused by nontoxigenic organisms may assist in developing future vaccines that both provide more certain protection against disease and also protect against carriage (asymptomatic infection).

There are surprisingly few published studies from which to establish the current recommendations for prophylaxis of contacts of diphtheria cases and treatment of carriers of *C. diphtheriae*. The most important issue, however, is the necessity to maintain vigilance (i.e., surveillance) to ensure that *C. diphtheriae* will not reemerge in those countries where it is now apparently absent. This requires maintaining the clinical and laboratory capacity to recognize and diagnose diphtheria and, crucially, improving levels of immunity among adults by increasing awareness among both the public and medical providers of the importance of regular tetanus–diphtheria boosters.

CHAPTER 15

Escherichia coli Diarrhea

Herbert L. DuPont, M. Teresa Estrada-Garcia, and Zhi-Dong Jiang

1. Introduction

During the 1940s and 1950s, a series of outbreaks of diarrhea in hospital newborn nurseries were reported in which the etiologic agent appeared to be *Escherichia coli* identified by serotype. These strains became known as enteropathogenic *E. coli* (EPEC). Since the Second International Symposium on EPEC in 1995, EPEC strains have been renamed typical EPEC (tEPEC) to distinguish them from another not well characterized *E. coli* strains known as atypical EPEC (aEPEC).[1] In this chapter we will focus on tEPEC although some general characteristics of aEPEC will be also mentioned.

Since the 1970s and 1980s, enterotoxigenic *E. coli* (ETEC) strains have been shown to be important causes of diarrhea among children living in developing countries and among international visitors to the areas (travelers' diarrhea). ETEC strains are being introduced into developing regions such as the United States.

Enteroinvasive *E. coli* (EIEC) strains have been identified in patients with dysenteric illness clinically indistinguishable from that produced by *Shigella* strains.

Enterohemorrhagic *E. coli* (EHEC) or Shiga toxin-producing *E. coli* (STEC) strains were shown to cause colitis with dysentery and to produce hemolytic uremic syndrome primarily in children. While the most common serotype of STEC is O157:H7, many other serotypes of shigatoxigenic *E. coli* can cause illness. Our food supply is currently an important source of STEC infection.

Herbert L. DuPont • Center for Infectious Diseases, The University of Texas – Houston School of Public Health, Houston, Texas, USA; St. Luke's Episcopal Hospital, Houston, Texas, USA; Baylor College of Medicine, Houston, Texas, USA. **M. Teresa Estrada-Garcia** • Department of Molecular Biomedicine, CINVESTAV-IPN, Mexico D.F. **Zhi-Dong Jiang** • Center for Infectious Diseases, The University of Texas – Houston School of Public Health, Houston, Texas, USA.

E. coli strains showing enteroaggregative attachment to epithelial cells and referred to as enteroaggregative *E. coli* (EAEC) were identified as causes of persistent diarrhea in infants living in developing countries, AIDS-associated diarrhea and travelers' diarrhea. EAEC strains have been implicated as causes of pediatric diarrhea in the United States.

There is a sixth potential classification of diarrheagenic *E. coli* showing diffuse attachment to tissue culture cells. These so-called diffusely adherent *E. coli* (DAEC) are currently being evaluated in cases of diarrhea. The pathogenicity of these strains is currently uncertain. DAEC will not be included in this review.

In this chapter, we will review information available about EPEC, ETEC, EIEC, STEC and EAEC. Since the organisms are biochemically similar—each represents an *E. coli*, they will be discussed in the same sections even though their clinical features and epidemiology are distinctly different.

2. Historical Background

In the 1940s serotype-identified *E. coli* were shown to cause nursery outbreaks of diarrhea. EPEC strains have since been shown to have a worldwide distribution. Serological procedures were first developed to define these EPEC strains according to their somatic (O) and flagellar (H) antigens; however, the strains are best defined on the basis of pathogenic characteristics of intestinal attachment and effacing histopathology.

Taylor et al.[2] reported in 1961 that *E. coli* isolated from stools of a number of children with a diarrheal syndrome caused dilatation from transudation of fluid and electrolytes in rabbit ileal loop preparations, while strains recovered from healthy infants, from well water or from the urine of patients with urinary tract infections produced a negative reaction. Table 1. Important *E. coli* Serotypes

EPEC	ETEC	EIEC	STEC	EAEC
O18:H7	O6:H16/$^-$	O28:H$^-$	O4:H$^-$	O3:H2
O20:H26	O8:H9/$^-$	O112:H$^-$	O5:H$^-$	O7:H$^-$
O25:H1	O15:H11/$^-$	O115:H$^-$	O16:H6	O15:H18
O26:H11/$^-$	O20:H$^-$	O124:H30/32/$^-$	O26:H11/21/32	O44:H18
O44:H34	O25:H42/$^-$	O136:H$^-$	O46:H31	O77:H18
O55:H6/7/$^-$	O27:H7/20	O143:H$^-$	O48:H21	O86:H$^-$
O86:H27/34/$^-$	O63:H12 or H$^-$	O144:H$^-$	O55:H7	O111:H21
O91:H7/$^-$	O78:H11/12/20	O147:H$^-$	O91:H10/21	O126:H27
O111H2/12/$^-$	O85:H7	O152:H$^-$	O98/H$^-$	O127:H2
O114:H10/32	O115:H11/40	O159:H$^-$	O111:H2/8/$^-$	
O119:H6/$^-$	O128:H7/21	O164:H$^-$	O113:H21	
O125:H21/$^-$	O148:H28	O167:H4/5/$^-$	O117:H14	
O126:H2/$^-$	O149:H10		O118:H12	
O127:H9/21/40/$^-$	O159:H20		O119:H6	
O128:H2/7/8/12/$^-$	O148:H28		O125:H$^-$	
O142:H6	O167:H5		O126:H8	
O158:H23	O173:H$^-$		O128:H2	
			O145:H$^-$	
			O157:H7/$^-$	
			OO172:H$^-$	

EPEC, enteropathogenic; ETEC, enterotoxigenic; EIEC, enteroinvasive; EHEC, enterohemorrhagic; EAEC, enteroaggregative. Multiple H types found in each category are indicated (e.g., H2/7/8/12/$^-$ indicates that H2, H7, H8, H12 and H$^-$ [non-motile] strains have been identified with the O group provided)

1970, an O148 strain of *E. coli* was reported to have produced diarrhea in British soldiers stationed in the Middle East. A closely related O148 *E. coli* strain was later shown to be enterotoxigenic causing diarrheal illness resembling mild cholera in volunteers.[3] In 1970, two different enterotoxins separated by heat susceptibility were shown to be produced by *E. coli* pathogenic for swine.[4] Colonization fimbriae were shown to confer an ETEC adherence capacity for epithelial cells.[5] ETEC strains have been shown to be the most important cause of diarrhea among international travelers from highly industrialized regions to developing countries.

EIEC strains were first demonstrated as causative agents of diarrhea in Japan[6] and Brazil.[7] The similarity of these strains to *Shigella* in causing bacillary dysentery was demonstrated in volunteer studies.[3] Widespread outbreaks of EIEC diarrhea have occurred in the United States[8–10] and other countries associated with contaminated food. EIEC strains have been shown to have a low level of endemic occurrence in cases of diarrhea in nearly all parts of the world. Similarly pathogenic features of EIEC diarrhea are almost identical to those of *Shigella* such as invasion of the colonic epithelium, intracellular multiplication and extension into adjacent epithelial cells.

STEC strains have emerged as a distinctive *E. coli* pathotype following two independent epidemiological observations in 1982 and reported in 1983. Riley et al.[11] reported two large gastrointestinal outbreaks in the United States associated with consumption of undercooked hamburgers served at "fast-food" restaurants. The outbreaks were characterized by occurrence of hemorrhagic colitis (severe abdominal pain and watery diarrhea followed by grossly bloody diarrhea with little or no fever) where stool cultures grew *E. coli* serotype O157:H7 that was not invasive or enterotoxigenic. The second report by Karmali et al.[12] described an association of sporadic case of hemolytic uremic syndrome (triad of acute renal failure, thrombocytopenia and microangiopathic hemolytic anemia) with enteric infection by an *E. coli*-producing cytotoxin activity on Vero cells (verotoxin). While the most common serotype of STEC strains is O157:H7, O26:H11 and many other serotypes may be identified in the enteric disease caused by STEC strains (see Table 1).

In 1985 HEp-2 tissue culture-adherent *E. coli* were found in an important percentage of US travelers to Mexico with diarrhea[13] helping to explain the observation that antibacterial drugs were beneficial in shortening travelers' diarrhea in those with otherwise pathogen-negative illness.

3. Methodology

3.1. Sources of Mortality Data

Little is known about the actual incidence and mortality of illness seen with diarrheagenic *E. coli* infection. It is necessary to rely on outbreak data and information obtained

from prevalence surveys. The mortality of EPEC diarrhea from earlier studies varied widely from 0 to as high as 70%. The average mortality rate has been reported to be 5–6%. An increased mortality, reaching 16%, has been seen in newborns particularly if illness is complicated by prematurity. EPEC strains appear to differ in virulence characteristics. *E. coli* O111 was shown to be associated with a striking clinical illness resulting in the common occurrence of fatalities.[14]

ETEC strains produce self-limiting disease in healthy persons from the industrialized countries traveling to most regions of the developing world, but severe cholera-like illness can occur.[3,15] Mortality is unusual with ETEC, but it undoubtedly occurs in areas of the world where health standards are low and where fluid and electrolyte replacement is not established in those with dehydrating illness. There are no accurate data defining expected EIEC mortality rates, but reported studies suggest that deaths would be unusual.

Uncomplicated STEC infection including dysenteric disease shows a low mortality rate. In a comprehensive community outbreak of O157:H7 infection, 3 of 501 (0.6%) cases died.[16] When complicated by the hemolytic uremic syndrome, STEC diarrhea is associated with a mortality rate of approximately 10%.

Enteroaggregative *E. coli* (EAEC) is an unusual cause of death with fatalities occurring primarily in patients with advanced AIDS.

3.2. Sources of Morbidity Data

Since *E. coli* diarrhea other than that caused by STEC is not a reportable disease, data on morbidity must come from survey information.

3.3. Surveys

Sporadic cases and community and hospital nursery outbreaks of EPEC diarrhea have been documented in nearly every country where appropriate studies have been carried out. Three types of studies have been done to determine the importance of EPEC illness: surveys of the relative frequency of recovering EPEC strains in populations with diarrhea; study of newborn nursery outbreaks of EPEC disease; and surveillance of EPEC strains during short periods in communities under study. While it is impossible to state the prevalence and incidence of diarrhea with accuracy, in approximately 10% of diarrhea episodes in infants and young children an EPEC strain can be recovered from stools.

Surveys of ETEC, EIEC, STEC and EAEC diarrhea have been restricted to short-term studies of diarrhea cases and outbreaks in several regions of the world.

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of Organisms. The methodology for *E. coli* isolation is readily available in microbiology texts, and any diagnostic laboratory that performs bacteriological isolation can isolate *E. coli* with proficiency. Biochemically, diarrheagenic *E. coli* are not distinct from the nonpathogenic *E. coli* present normally in the intestine. *E. coli* strains that cause illness can only be differentiated from normal flora strains by the demonstration of a virulence property. This has always presented a problem for the routine clinical bacteriology laboratory because demonstration of *E. coli* virulence properties or *E. coli* pathotypes requires methodology generally available only in research and reference laboratories. This diagnostic problem has limited what we know about the epidemiology of *E. coli* diarrhea, although recent advancements in molecular techniques have greatly improved our diagnostic capabilities.

Complete serotyping of *E. coli* strains requires a determination of both the O and H antigen types. There are approximately 164 O groups and 57 H groups. Table 1 lists the O (somatic) and H (flagellar) serotypes identified with EPEC strains. Virulence assays have largely replaced serotyping for the identification of EPEC strains.

ETEC are diagnosed by the demonstration of the production of one or both of the enterotoxins that they produce. Generally, five *E. coli* colonies per patient-sample need to be tested for both toxins. Immunoassays have been developed for detection of ST, including a radioimmunoassay and an enzyme-linked immunosorbent assay (ELISA). These tests correlate well with results of the sucking-mouse assay and require less expertise. As early as 1982, DNA probes were found to be useful in the detection of LT- and ST-encoding genes in stool and environmental samples.[17] More recently advances in ETEC detection have been made including PCR assays which are sensitive and specific when used directly on clinical samples or on isolated bacterial colonies. A useful adaptation of PCR is the multiplex RCR assay[18] in which several PCR primers are combined with the aim of detecting one of several different diarrheagenic *E. coli* pathotypes in a single assay. Following study with a multiplex PCR, various reaction products can be differentiated by single agent assay.

Presence of a virulent *Shigella* or EIEC strain traditionally has been verified by testing in the guinea pig eye (Sereny) model. In the assay, a heavy suspension of bacteria was dropped into the conjunctival sac of a guinea pig and 1–7 days later observed for presence of purulent keratoconjunctivitis confirming the strain capacity to invade epithelial cells. DNA probes and PCR methods are now available to test directly for the presence of genes encoding for invasiveness.

The presence of STEC O157:H7 strains, the most common serotype in the United States, is determined by isolating sorbitol non-fermenting *E. coli* and verifying the isolated colonies as being O157 positive by agglutination reagents and inhibition of motility in media containing H7 antiserum.[19] Since other serotypes of Shiga toxin-producing *E. coli* may cause illness, either *E. coli* colonies or stool samples should be checked for the production of Shiga toxin by enzyme immunoassay or PCR. If positive for Shiga toxin, they should be sought by culture methods so that sero- and molecular typing can be performed for epidemiologic study.

EAEC strains are identified either using the HEp-2 cell adherence assay or by looking for one or more virulence properties by DNA probe, ELISA or PCR methods.[20, 21] The gold standard for EAEC identification remains the HEp-2 adherence test. This test requires specialized facilities and can therefore only be conducted in reference laboratories. Baudry et al.[22] developed a DNA probe, CVD432, to simplify the identification of strains of EAEC. The CVD432 probe has been shown to have sensitivity for detecting EAEC isolates of between 15 and 99% from various studies carried out in different regions of the world. Tsukamoto[23] proposed a PCR method based on the *aggR* regulatory gene. Although *aggR* is a sensitive target, it may be less specific than the CVD432 locus. The HEp-2 adherence assay and/or the CVD432 standard probe represent the present means for detecting EAEC; however, it is clear that more sensitive, specific and practical methods are needed to improve diagnosis of infected cases and understanding of the disease.

Multiple laboratories are working on the refinement of reagents allowing the detection of diarrheagenic *E. coli* using multiplex polymerase chain reaction (PCR) methods.

In ETEC diarrhea, seroconversion to anti-LT antibody is common but not invariable. An ELISA was developed for the detection of IgG and IgM antibodies to ETEC LT.[24] Anti-LT antibody was associated with previous infection by LT-producing strains of ETEC. The ELISA technique also allows the study of humoral antibody development directed to colonization factor antigens during ETEC infection.

During infection with EIEC, a serological response can be documented.[3] In view of the similarity to bacillary dysentery, most probably the frequency of seroconversion will correlate with the presence of dysentery (passage of small volume bloody mucoid stools), which indicates the colonic mucosal invasion and inflammation.

An ELISA has been developed to detect serum antibodies against *E. coli* O157:H7.[25] This assay has been used along with culture to increase detection of this STEC strain.

Serology has not yet been employed to detect EAEC infection.

4. Biological Characteristics of the Organisms

Volunteer experiments have been conducted to establish the virulence of EPEC strains.[26] EPEC strains have been defined as specific serogroups of *E. coli* that have been epidemiologically incriminated as causes of diarrhea but do not produce conventional enterotoxins and are not invasive. The O:H serogroups recognized as EPEC are listed in Table 1. Biopsies from children infected with an O119 EPEC strain have shown a characteristic lesion consisting of localized adherence of microcolonies, cupping of the enterocyte and destruction of the microvilli.[27] Cravioto et al.[28] developed a tissue culture model for this adherence property using HEp-2 cells. The focal attachment of the strains to small intestinal epithelial cells has been shown to be associated with a pathognomonic lesion at the site of attachment described as attaching and effacing histopathology with microvillus destruction, intimate adherence of bacteria to intestinal epithelium, pedestal formation and aggregation of polarized actin at the site of attachment. Molecular pathogenicity of EPEC infection has been described.[29] There are two chromosomal factors and one plasmid constituent that are essential. The plasmid factor is the bundle forming pilus (*bfp*) that leads to focal attachment of membrane receptors and growth as focal microcolonies. The chromosomal factors are carried on the locus of enterocyte effacement (LEE) and include type III secretory system, *E. coli* secreted protein (Esp), translocated intimin receptor (Tir) that is inserted into the intestinal membrane as a novel organism receptor and the *eae* gene, encoding intimin, which is responsible for the tight epithelial attachment and loss of microvilli (the "attaching and effacing" property). LEE also carries tyrosine kinase which together with Ca^{++} leads to formation of actin-rich pedestals. A DNA probe using *eaf* plasmid fragment is available to screen for EPEC strains as well as PCR primers to identify *bfp* gene. *E. coli* strains that possess the *eae* gene but are negative for the plasmid *bfp* are associated with diarrhea and are known as atypical EPECs.

ETEC strains produce one or both of two enterotoxins, a heat-labile toxin (LT) or a heat-stable toxin (ST). LT resembles cholera toxin, which operates through adenylate cyclase mechanisms, and the second, ST, which is a poorly antigenic, small molecular weight toxin, works through guanylate cyclase stimulation. LT and ST are under plasmid control. ETEC strains may produce LT or ST or both. Some strains that only produce LT show reduced pathogenicity. LT is detected by showing dilatation of a rabbit ileal loop, by showing morphogenic changes in certain cyclic AMP-dependent tissue cultures (adrenal cells, Chinese hamster ovary) and in serologic procedures like in an enzyme-linked immunosorbent assay (ELISA). ST has been traditionally assayed in a suckling mouse model. There exist gene probes,

which can detect genetic material related to the plasmids of LT and ST toxigenicity. Surface protein adhesions, known as colonization factor antigens (CFAs), allow ETEC to attach to intestinal mucosa. One of about 18 defined CFAs are found on the surfaces of between 50 and 80% of ETEC strains found worldwide. Strains of ETEC in a community differ widely in terms of virulence properties suggesting the presence of multiple strains in endemic settings.[30]

EIEC strains possess a *Shigella*-like invasive property that probably represent the important biological activity favoring persistence in nature. This ability to invade epithelial cells is also encoded by genes carried on a plasmid and are the same as those found in *Shigella*. The resemblance of these strains to *Shigella* is further seen in their possession of common antigens. There is a relationship between EIEC and *E. coli* serotype. Table 1 lists the recognized EIEC serotypes. It is unknown why these strains are not more important causes of illness.

The important virulence property of STEC appears to be Shiga toxin (Stx) production. It is not clear if the possession of genes encoding Stx confers pathogenicity. Epidemiological studies have shown an association with disease with STEC strains that actively produce one or both STxs.[31] The term enterohemorrhagic *E. coli* (EHEC) was proposed to denote those STEC strains that cause hemorrhagic colitis and, like infection caused by *S. dysenteriae* 1, the hemolytic uremic syndrome (HUS). Furthermore, EHEC or STEC strains like EPECs cause the attaching and effacing intestinal lesions on epithelial cells and some possess a 60-MDa plasmid that encodes for an hemolysin. STEC diarrhea is complicated by HUS in 2–10% of patients (especially children 1–5 years of age and among the elderly in nursing homes). Therapy of EHEC illness with certain antimicrobial agents (e.g., trimethoprim and fluoroquinolones) may predispose to HUS by encouraging the production of Stx, making therapeutic recommendations difficult. Not all antibacterial drugs appear to predispose STEC infection to development of HUS. STEC strains in the United States often belong to serotype O157:H7 or O157:H$^-$. EHEC belonging to O157 serotype characteristically do not ferment sorbitol, while >70% intestinal floral *E. coli* do. STEC belonging to other serotypes (non-O157) often ferment sorbitol like normal flora. STEC produce one or both Shiga toxin 1 (Stx 1) and Shiga toxin 2 (Stx 2). Stx 2 may be more pathogenic and more important in the production of HUS. To properly screen EHEC strains in cases of diarrhea, stool should be plated on MacConkey-sorbitol media and sorbitol-non-fermenting *E. coli* screened for O:157 LPS serotype. In addition, the stool sample should be tested directly for presence of Stx 1 and Stx 2 by EIA. There are reports from Europe of Shiga toxin-negative *E. coli* O157:H$^-$ causing HUS. EHEC infections are more common in the Northern and Northwestern United States. Two-thirds of symptomatic STEC infections are associated with the passage of bloody stools (dysentery), fever is characteristically absent with leukocytosis and abdominal tenderness commonly found. The highest incidence of disease is in the 5–9 years age group.

EAEC are increasingly being recognized as a cause of diarrhea in developing countries, especially persistent diarrhea in children and acute travelers' diarrhea. The organism may cause foodborne outbreaks in industrialized regions and appears to be an important cause of diarrhea in patients with AIDS worldwide. The organisms show an aggregative pattern of attachment ("stacked brick" appearance) in the HEp-2 cell assay with bacteria adhering to the cells and the glass substratum. The organisms often produce an inflammatory intestinal response as determined by presence of fecal lactoferrin and cytokines (interleukin 8 and IL-1b) during infection. The importance of mounting an IL-8 inflammatory response is seen in persons with a single-nucleotide polymorphism (SNP) in the promoter region of IL-8 gene who show an increased genetic susceptibility to EAEC diarrhea.[32] A variety of EAEC virulence factors have been described[20] explaining the propensity for virulent strains to produce diarrhea (see Pathogenesis and Immunity). Many EAEC do not possess these properties and may be avirulent. Foods in developing countries are commonly contaminated with the organism. A fluoroquinolone antibacterial drug and rifaximin were shown to be beneficial in shortening the diarrhea associated with EAEC infection in adult patients with AIDS and in travelers with diarrhea.[33,34] Human pathogenicity of at least one EAEC strain has been confirmed in adult volunteers.[35]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

The frequency of EPEC in stools of pediatric diarrhea is higher when hospital cases were compared to outpatients.[36] In the reports with the highest frequency of EPEC disease, a single strain usually could be identified in many of the cases, indicating a community-wide epidemic. Three geographically distinct areas were involved in one outbreak. In the three epidemic census tracts, attack rates were 73, 118 and 55 per 1,000 among nonwhite infants less than 1 year of age. Among index households, 50% had one or more asymptomatic pharyngeal carriers of the epidemic strain, while next-door neighbors and distant community household members harbored the strain in the pharynx in 33 and 0%, respectively. Intestinal carriage in the three different household groups was 18, 3 and 0%, respectively. Kessner et al.[37]

carried out a prospective examination of EPEC in a defined geographic area in Illinois and Indiana. An extensive community epidemic of diarrhea due to *E. coli* O111 during the summer, autumn and winter of 1960 and 1961 was documented. Age-specific attack rates for the 0- to 6-month-old age group ranged from 1,800 to 3,700 per 100,000. Carrier rates of asymptomatic contacts of index cases ranged from 5 to 10%. Pal et al.[38] described a community outbreak that occurred in India. The population morbidity rate was 0.16%, with age-specific attack rates for the 0- to 2-year-old age group of 0.98% and for the 6- to 11-month-old age group of 2.4%. During another community outbreak in Atlanta, EPEC strains were isolated from 12.7 per 1,000 persons at risk and from 125 per 1,000 infants less than 1 year of age. EPEC strains have been shown to be responsible for both epidemic and sporadic diarrhea.

While ETEC has been reported to cause a low frequency of diarrhea in the United States and Canada recently outbreaks of illness have been identified.[39] ETEC strains may produce epidemics of diarrhea. Such epidemics have been associated with the consumption of food or water contaminated with ETEC.[40] Also, outbreaks have been documented in hospital nurseries.[41] ETEC infection is more common in developing countries. The worldwide frequency of occurrence of bouts of ETEC diarrhea is estimated to be in the range of 650 million cases per year resulting in death in up to 380,000 children under 5 years of age. These organisms were the most frequently isolated pathogen among Mexican children with diarrhea.[42] Latin Americans possess high serum antibody titers to LT, while North Americans possess relatively low antibody titers.[24] The titer of LT antibody most probably reflects prior exposure to LT-producing *E. coli* and directly relates to resistance to infection. In a study carried out in rural Egypt, the incidence of ETEC infection was 1.5 episodes per child per year accounting for 66% of first episodes of diarrhea after birth.[43] ETEC strains were shown to be the most important cause of diarrhea among US travelers in Latin America,[44,45] being responsible for 40–60% of disease. As persons from the United States remain in endemic areas, they develop resistance to ETEC infection and diarrhea.

EIEC strains are unusual causes of endemic or epidemic diarrhea. Outbreaks associated with food contaminated with EIEC have been documented in the United States. EIEC has also been shown to be a cause of endemic diarrhea in Brazil[7] and among travelers to developing nations.[46]

STEC has been incriminated in both endemic and epidemic diarrhea in the United States, Canada, Europe and Japan. Outbreaks have occurred in nursing homes, day care centers, schools and the community; this class of pathogens also causes sporadic cases of colitis. Outbreaks of STEC have been associated with ingestion of inadequately cooked hamburgers, unpasteurized apple juice, wading pools, drinking water and produce. Recently exposure to animals in petting zoos has become a risk for infection. During 2005 and 2006, contaminated lettuce and spinach became an increasing risk for STEC disease transmission.[47]

EAEC are known to be important causes of diarrhea in certain high-risk groups. The strains cause between 10 and 20% of travelers' diarrhea[48] and an uncertain percentage of diarrhea in patients with advanced HIV infection.[49,50] A study of children with diarrhea carried out in Cincinnati between 1998 and 2000 revealed that EAEC strains were more commonly identified in inpatient children (5%) and children visiting emergency departments (10%) than in well children studied (1.4%).[51] Since routine diagnostic microbiology laboratories do not look for this organism we know very little about the frequency of occurrence in most populations.

5.2. Epidemic Behavior and Contagiousness

EPEC strains have a predilection for spread within hospitals, particularly in newborn nursery populations. Although the organism is spread within the community, the hospital probably plays a role in transmission to community members.[36]

Communicability of ETEC strains from person to person is not likely to occur[52] because of the high inoculum required for disease.[3] Epidemiologic and microbiologic investigations have implicated contaminated food as the most common vehicle for ETEC infection.[53–55] ETEC infections in areas of endemic infection tend to be clustered in warm, wet months, when multiplication of ETEC in food is most efficient.

Epidemic behavior and contagiousness of EIEC strains are unknown.

Very large point source outbreaks of STEC serotype O157:H7 have been recognized.[7,12] Other EHEC serotypes have been shown to cause endemic diarrhea and epidemic disease. Intrafamilial secondary transmission of O157:H7 has been documented to be ~10% during community outbreaks.[16]

EAEC is a high-inoculum[35] foodborne[55] disease. Person-to-person spread should occur only rarely if at all.

5.3. Geographic Distribution

EPEC diarrhea occurs with a worldwide distribution. The first large outbreaks were recognized in industrialized urban parts of the world. This may have been due to greater reporting with improved identification techniques. EPEC diarrhea has also been reported in studies of endemic diarrhea in developing countries. tEPEC is an uncommon

cause of diarrhea in industrialized countries most often found in children with diarrhea in these countries whereas in recent years atypical EPEC (aEPEC) strain identification in industrialized countries has increased.[1] Furthermore, tEPEC continues to be an important agent responsible for infantile diarrhea in developing countries. In recent years aEPEC has been associated with diarrhea documented in Mexico[56] and Brazil.[1]

Endemic ETEC diarrhea has been shown to be common only in the developing world. ETEC strains cause low level endemicity with occasional outbreaks in the United States. ETEC diarrhea has been reported to occur with high frequency in Latin America, Southern Asia and Africa.

EIEC strains have a worldwide distribution, but have been reported to be a frequent cause of diarrhea only in Brazil.[7]

STEC are predominately seen in the developed nations. The incidence of the organism in developing countries appears to be lower than in industrialized areas although strains have occasionally been isolated from patients with diarrhea in these regions.[56]

EAEC strains occur worldwide. As with many other bacterial enteropathogens, EAEC infection rates may be most common in developing regions where enteric disease is hyperendemic.[56–58] In Brazil, EAEC have been implicated in up to 68% of cases of persistent diarrhea in infants and the pathogen has been associated with deaths associated with diarrhea. EAEC have also been implicated as causes of sporadic diarrhea in Mexico, Chile, Bangladesh and Iran.

5.4. Temporal Distribution

EPEC diarrhea occurs year-round, with a summertime peak incidence. The time of year probably does not greatly influence disease rates.

ETEC diarrhea has been reported more commonly during warmer summer months which may relate to the season when most studies have been carried out. In two semitropical countries, Mexico and Morocco, ETEC infection appeared to be most common in rainy summer months.[59,60]

There is no information about the temporal distribution of EIEC, STEC or EAEC infections. As with other bacterial enteropathogens these infections are likely to be more common in the warmer summer months.

5.5. Age

One study examining the relationship of age to EPEC infection demonstrated that the median age at the time of hospitalization was 8 months and 2 weeks.[37] The distribution by age groups of hospitalized children was 86% between 0 and 18 months, 65% under 1 year of age and 9% in the neonatal period. In the community survey, the age distribution of those with positive stool cultures, regardless of symptoms, mirrored the age group hospitalized for diarrhea. Most published studies have confirmed that nearly all episodes of culturally confirmed EPEC diarrhea are seen in infants under 2 years of age, with more than half being in the group less than 6 months of age. In Houston, EPEC disease was documented to occur 20 times more frequently in infants below 6 months of age compared to children 1–2 years of age.[61] One study indicated that approximately 25% of infants were infected with an EPEC strain during the first year of life, and the prevalence of EPEC intestinal infection by a group of infants less than 1 year of age was 1%.[62]

In ETEC diarrhea, most cases of infection occur in children in areas where disease is endemic, as determined by the natural history of antibody to LT during the first 3 years of life plus the observation that adults living in these areas are immune to infection. In endemic areas, the highest attack rate of ETEC infection occurs in the age group 6–36 months of age, with decreasing rates with increasing age.[63] Although ETEC infection occurs most frequently in infants, immunological naïve adults are susceptible. ETEC is the predominant etiologic agent causing travelers' diarrhea among adults from the developed world visiting areas where ETEC is endemic.[64] Studies suggest that 20–60% of such travelers experience diarrhea with 20–40% of cases being due to strains of ETEC.

No information is available about the relationship of age to EIEC diarrhea. Like all foodborne bacterial diarrheas, it is likely to be most common in young children and in any age group consuming food contaminated by the organism.

While STEC can infect any age group, STEC diarrhea is most common in children. Hemolytic uremic syndrome following STEC infection characteristically occurs in children although this complication also occurs in the elderly.

Association of age with EAEC diarrhea has not been studied. Clearly all age groups are susceptible to EAEC diarrhea.

5.6. Sex

As with many other infections, males of all ages show a higher infection rate due to EPEC strains. An overall male–female ratio of 4:1 has been reported.[36] Insufficient information is available to determine whether a sex relationship exists for the other diarrheal diseases due to *E. coli*.

5.7. Race

The published studies show a correlation of EPEC infection with exposure to hospitals and crowded living conditions, which probably explains the greater occurrence

of EPEC infections in nonwhite children in the United States.[36]

Insufficient data are available to determine whether there are racial influences on rates of ETEC, EIEC, STEC and EAEC diarrhea; however, race is not likely to be a risk factor for these enteric infectious diseases.

5.8. Occupation

EPEC is a disease of infants. Those persons taken into tropical climates by their employment might be expected to be at risk for ETEC disease. Occupational factors relating to exposures to EIEC, STEC and EAEC are unknown.

5.9. Occurrence in Different Settings

EPEC strains produce diarrhea primarily in hospital populations, particularly in nurseries housing newborn infants. Hospitalized infants and children attending day care centers represent the major reservoirs for community spread.

ETEC diarrhea is a particular problem among groups traveling from low-risk areas (e.g., United States, Northwestern Europe, Canada, Australia, New Zealand and Japan) to high-risk areas (Latin America, Southern Asia and Africa). It is also a problem among infants and children in these high-risk areas. Hospital outbreaks of ETEC diarrhea have been reported.[41]

EIEC organisms have been reported as a rare cause of foodborne outbreaks in the United States.[8–10] These organisms are uncommon causes of diarrhea in most parts of the world. In Brazil there appears to be an unexplained high prevalence of EIEC-associated diarrhea.[7]

STEC diarrhea and dysentery have been shown to occur primarily in developed nations.[11]

EAEC strains have been identified in travelers with diarrhea to a variety of countries,[48] in children from developing countries,[42,56,57] in AIDS-associated diarrhea in the United States and Africa and in infants in developing countries.

5.10. Socioeconomic Factors

Socioeconomic factors are important in EPEC diarrhea primarily as they influence crowding, sanitation, breastfeeding practice and exposure to hospitals. There is no known relationship between socioeconomic factors and other diarrheal diseases due to *E. coli*, although it can be assumed that reduced socioeconomic level would relate to increased rates of diarrhea due to each of the diarrheagenic *E. coli*.

6. Mechanisms, Routes of Transmission and Reservoirs

Within hospital environments, EPEC organisms are transmitted by direct contact, spread by dust and by fomites. During one outbreak of diarrhea due to an EPEC strain, nursing personnel and family members were shown to be asymptomatically infected with the epidemic strain,[65] suggesting a possible role in the transmission of the agent. In the same study, recovery of an EPEC from stools of mothers just before delivery was documented in 13%, with subsequent isolation of *E. coli* with the same serotype from 40% of the newborn infants of the culture-positive mothers. Asymptomatic adult carriers of EPEC strains undoubtedly play a role in disease transmission to infants and young children. During one community epidemic, the infecting strain was commonly isolated from pharyngeal cultures, and respiratory symptoms were noted.[65] As is the case with other enteric pathogens, an association of respiratory symptoms and EPEC diarrhea has been reported. It is possible that a respiratory route of transmission may play a role in disease transmission with this and other enteropathogens. EPEC strains as with other enteric pathogens are spread by the fecal–oral route of transmission. Person-to-person contact spread has been suggested by the epidemiological patterns of EPEC infection. Typical EPEC serotypes have not been found in animals, suggesting that humans are the only living reservoir for these organisms.[1] In contrast, most atypical EPEC serotypes have been isolated from a variety of animal species and likely both humans and animals may serve as reservoirs for aEPEC.[1]

ETEC strains are characteristically spread through ingestion of contaminated food.[53–55,66] In our studies in Mexico, when students ate at public eating establishments, they were more likely to develop ETEC diarrhea than if they consumed meals prepared by themselves in their own apartments. Food sampled from public eating facilities was commonly found to be contaminated with ETEC.[53–55,66] Due to the large inoculum necessary to produce diarrhea in healthy adults ($>10^8$ viable cells),[3] it is likely that food and less likely water are the important vehicles of disease transmission. Only humans have been described to be reservoirs for human ETEC.

The important transmission kinetics of EIEC is unknown, largely because of the rarity of infection by these strains. The major documented outbreaks have been associated with consumption of food contaminated with these organisms.

It is known that STEC strains can commonly be identified on the surface of beef secondary to enteric infection of cattle by the organisms.[11,16] Lake and wading pools may be a source of infection. Other foods and beverages including

drinking water may be the source of infection.[67] A variety of animals including sheep, pigs, goats, cats and dogs can harbor STEC strains in their intestine, but cattle are considered to be the most important animal species in terms of human infection.

The source of EAEC strains in developing regions is likely food.[55]

7. Pathogenesis and Immunity

Several histopathologic studies have shown that there is a characteristic lesion associated with EPEC infection.[27] The EPEC are seen by electron microscopy as microcolonies that adhere to epithelial cells with destruction of the brush border, but with no evidence of invasion. Pedestal formation has also been noted. This lesion can be duplicated in an animal model[68] and there is a tissue culture model of infection (HEp-2 cell assay).[28] This adherence property is encoded for by genes carried on a plasmid known as the EPEC adherence factor (EAF). The EAF plasmid encodes a type IV pilus called the bundle-forming pilus (BFP) which mediates adherence. Production of toxins has been described for EPEC strains and the intestinal lesion suggests damage from unrecognized toxins. Although EPEC strains appear to produce illness in adults, the disease is primarily a disease of newborns and young infants. The age distribution suggests that protective immunity develops. The nature and extent of immunity are unknown.

Prior to the development of illness, ETEC strains must colonize the toxin-sensitive upper intestine before elaborating secretory enterotoxins. Specific fimbrial antigens on the surface of ETEC strains have been shown to mediate adherence of the *E. coli* to the mucosa of the small bowel. Table 2 lists the recognized colonization factor antigens of ETEC according to natural hosts. In the small intestine of piglets, the K88 antigen appears to bind to a receptor on the villous epithelial cells.[69] Attachments of ETEC to the upper gut depend not only on the fimbriae of the bacteria but also on the presence of specific receptors for the fimbriae.[70] Some strains of pigs genetically lack the receptor for K88, making them immune to disease caused by K88-bearing organisms. Antigenically different fimbriae, K88, K99, 987-type and type 1 (common) pili, adhere equally to porcine intestinal epithelium.[71] These ligands probably bind to different receptors in view of a lack of competitive inhibition of bacterial adherence. ETEC strains infecting humans usually possess one of several recognized colonization factor antigens known as CFA/I, II, III and IV and putative colonization factors (e.g., PCFO159 and PCFO166).[72]

Table 2. Adherence Fimbriae of Enterotoxigenic *E. coli* (ETEC)

Natural Host	Colonization Factor Antigen (CFA)	Coli Surface (CS) Adhesin
Piglet		K88
Calf, lamb		K99
Piglet		987-type
Human	CFA I	
	CFA II	CS 1, CS2, CS3
	CFA III	CS 8
	CFA IV	CS4, CS5, CS6
		Miscellaneous surface adhesins: CS7, CS12 (PCFO159), CS14 (PCFO166), CS17

Natural immunity to ETEC infection occurs when persons remain at high risk for infection. In a study of students attending school in Mexico, the attack rate was inversely related to the length of time the student had lived in the endemic area.[44,73] Newly arrived students from the United States suffered from diarrhea at a rate of 40% per month, compared to a rate of 20% for the same time period for those students from the United States who had been in Mexico for approximately a year or longer. Newly arrived students from Venezuela did not show an increase in illness, indicating immunity from prior exposure in Venezuela to agents prevalent in Mexico.[73] A decreased frequency and lowered severity of illness among Latin American students correlated with an apparent resistance to ETEC infection. An inverse relationship was found between the geometric mean antibody titer (GMT) to LT and the occurrence of diarrhea associated with LT-producing *E. coli*.[24] The lack of exposure to ETEC in the United States appears to explain the remarkable susceptibility to infection among persons from the United States traveling in developing countries. Immunity to ETEC infection does not appear to be strictly antitoxic in origin, since Latin American students exposed to ETEC strains rarely excrete the organism in stools asymptomatically, in contrast to the common finding of asymptomatic fecal shedding of strains in newly arrived US students.[44,74] These data suggest that antibacterial immunity is operative because virulent strains are excluded from gut colonization. This could represent intestinal antibody to adhesion of fimbriae and/or somatic antigens or other factors.

The pathogenic mechanisms of EIEC are the same as those of *Shigella*. These organisms invade the colonic mucosa and spread laterally in the epithelium, causing ulcer formation and clinical dysentery. It can be assumed that immunity to EIEC is similar to that seen in shigellosis where immunity is known to be serotype specific.

E. coli O157:H7 strains have been shown to elaborate important quantities of Shiga-like toxin that is thought to be responsible for the tissue damage seen in this infection. Serum antibodies to Shiga-like toxin and to lipopolysaccharide of the O157 antigen have been demonstrated in patients with STEC diarrhea.[25]

EAEC possess a range of virulence properties involved in three stages of disease production: adherence to intestinal mucosa; increased production of mucus; and production of an intestinal inflammatory response.[75,76] Adherence is mediated by plasmid-controlled fimbriae and other adhesins that have been partially characterized.[76,77] Strains producing infection and disease are characterized by their heterogeneity.[20,77,78] Aggregative attachment is important in EAEC strains and a wide number of virulence factors have been found with EAEC strains isolated from human subjects. A number of putative and known virulence have been described. Mucosal adherence appears to be related to production of a variety of adhesins including fimbrial structures referred to as aggregative adherence fimbriae (AAF) important to the aggregative adherence capacity of the organism and nonfimbrial adhesins. AAF secretion apparatus transports to the mucosal surface where dispersin protein appears to be important in local dispersal of the bacteria. Many EAEC strains harbor chromosomal factors including mucinase (Pic) and *Shigella* enterotoxin 1 (ShET1) and enteroaggregative heat-stable enterotoxin 1 (EAST-1) and the plasmid autotransporter cytotoxin, Pet. EAEC induce an inflammatory response with release of IL-8 from epithelial cells possibly mediated by presence of bacterial flagellin. Adherence is encoded in some EAEC strains by the adherence plasmid pAA including aggregative adherence fimbriae AAF/I and AAF/II. Nataro has described a transcriptional activator which controls virulence factor expression in a large number of pathogenic strains of EAEC.[20] The fact that no one virulence factor is found in all pathogenic strains of EAEC and that EAEC strains with definable virulence properties are commonly isolated from persons without symptoms complicates the field.

An interesting line of research has dealt with genetic differences in susceptibility to enteric infection. Based on the finding of high levels of IL-8 in stool samples of persons with bacterial diarrhea our group has looked at IL-8 genes and susceptibility to infection and diarrhea by these bacterial pathogens. Presence of polymorphism in the promoter region of the IL-8 gene was shown to be associated with increased susceptibility to EAEC diarrhea.[32]

8. Patterns of Host Response

In EPEC infection, unapparent infection and transient colonization are common, especially among older children and adults. In one study, 15–20 per 1,000 normal children between birth and 5 years of age harbored an EPEC strain in their stools.[62] In a 1-year longitudinal study of 40 households, transient excretion, infection defined as excretion longer than 4 weeks, and clinical illness were most common in young children.[79] The rate of excretion of EPEC in this study was approximately 11% in children under 1 year of age, while the rate in adults was 5%. Overt illness was seen in 25% of children under 1 year of age who had an EPEC detected in their stools. Illness is uncommon in older children and adults, even though they often carry the organism.

Asymptomatic ETEC infection commonly occurs in persons exposed to these strains in endemic areas.[44,74] It appears that highly susceptible individuals most commonly develop overt disease when exposed to ETEC strains, in contrast to those partially immune, in whom excretion without illness characteristically occurs, and to those with natural immunity through prior exposure, in whom neither disease nor excretion can be documented.

Asymptomatic excretion of EIEC was shown to be common in experimentally challenge in volunteers and seroconversion occurred without overt illness.[3]

STEC are low-dose pathogens causing illness in a high percentage of exposed persons. For unclear reasons, STEC diarrhea is most common in industrialized regions where children are exposed to the organism in food, water or from person-to-person spread.

All patient groups appear susceptible to EAEC strains. In highly endemic areas, such as Mexico, symptomatic disease occurs early after exposure followed by low rates of illness in the face of high infection rates.[80] Recently a study documented that EAEC diarrhea occurred commonly in US children.[51] Our group found that the presence of *aggR*-dependent virulence factor was associated with the presence of enteric symptoms. These data support heterogeneity of virulence among strains defined as EAEC by adherence assay.[78] As already presented, persons positive for a single-nucleotide polymorphism at the IL-8 promoter region are associated with increased rates of EAEC diarrhea among US students in Mexico.[32] These data suggest that both host and strain factors may contribute to susceptibility.

8.1. Clinical Features

While there is marked variation in the duration and severity of EPEC illness, the most common findings are fever (60%), diarrhea (>90%), respiratory symptoms (50%), abdominal distension suggesting paralytic ileus (10%) and rarely convulsions (<1%).[37] Dehydration may be seen in one-third of cases, especially in infants under 1 year of age, and hypernatremia and metabolic acidosis occur. Dysentery

has been reported in some cases of EPEC diarrhea. Illness usually lasts about 1 week, yet protracted illness commonly occurs and the illness may result in fatalities.[14,36] In fatal cases and in certain outbreaks of more virulent disease, a picture of septicemia and widespread intestinal inflammation and necrosis are found. A more severe disease with a higher percentage of fatalities has been seen in infection with the O111 serogroup of *E. coli*.[14,79] Mortality is higher for ill infants who are less than 1 month of age.[37]

In ETEC diarrhea, the disease resembles mild cholera in most cases, where the most common finding is watery diarrhea. In contradistinction to cholera, abdominal pain and cramps are common in *E. coli* diarrhea and may be severe and low-grade fever may be seen. An inflammatory nature of the intestinal lesion in ETEC diarrhea is suggested by the finding of fecal cytokines in naturally occurring illness.[81] In our experience in Mexico, the average untreated illness in adults consists of passage of 8–12 unformed stools over a 4- to 5-day period.[73] In volunteers with experimentally induced illness, the clinical syndrome in the most severe cases consisted of passage of 5–10 watery stools per day, lasting as long as 19 days. We have seen a patient in Houston with ETEC infection present with a cholera-like illness requiring more than 30 l of intravenous fluids to maintain hydration. Of significance was that this person had had a previous gastric resection for peptic ulcer disease. Fatalities are unusual with ETEC disease and probably occur only in the very young, the elderly and those with marginal cardiovascular reserves. The illness associated with ST-only (strains that produce only ST) *E. coli* appears to be quite similar to that produced by ST/LT strains.[41]

EIEC strains produce an illness indistinguishable from shigellosis (bacillary dysentery). Fever, abdominal pain and passage of bloody mucoid stools are frequently seen.[3]It seems that EIEC severity can be increased in malnourished children coinfected with other pathogens.[82]As in shigellosis, the disease is usually self-limiting, and fatalities are probably unusual.

Hemorrhagic colitis secondary to STEC infection is a distinctive clinical syndrome.[11] It normally starts as watery diarrhea with abdominal cramps and progresses in a majority of cases to grossly bloody diarrhea with little or no fever. The average duration of symptoms is around 8 days. There does appear, however, to be a spectrum of clinical disease with some patients having only watery diarrhea with no blood in the stool or fever. STEC infection has also been associated with hemolytic uremic syndrome as a common sequela to infection with these organisms.[11]

EAEC is a non-invasive but inflammatory pathogen characteristically causing watery diarrhea without high fever or dysentery.

8.2. Diagnosis

The features of *E. coli* infections relevant to diagnosis are summarized in Table 3. EPEC diarrhea should be considered in any outbreak that develops in a hospital nursery or on a pediatric hospital ward. In this setting, serotyping or virulence testing of *E. coli* isolated from affected infants may identify the outbreak strain. Because of a variable clinical syndrome depending on strain virulence and host response, any diarrheal illness in a hospitalized pediatric population should be considered as potentially EPEC in origin. Serotyping or virulence testing of *E. coli* from children with sporadic community-acquired diarrhea does not justify the cost. More studies need to be conducted to determine the importance of the HEp-2 cell adherence assay and the EAF probe in detecting EPEC strains in endemic diarrhea.

ETEC intestinal infection should be considered in any traveler from a low-risk area such as the United States, Canada, Northwestern Europe, Australia, New Zealand or Japan who develops diarrhea without high fever while traveling in Latin America, Southern Asia or Africa. Unfortunately, the routine diagnostic laboratory is presently unable to assay for LT and ST, which are available only in research and reference laboratories. ELISAs, DNA probes and PCR methods are now being developed for use in the routine diagnostic laboratory.

EIEC infection should be suspected in a patient with bacillary dysentery (passage of small volume bloody mucoid stools with prevalent fecal leukocytes on microscopic examination) in whom stool cultures are negative for *Shigella* and *Campylobacter*. The routine diagnostic laboratory can make a presumptive identification of EIEC by the biochemical reactions of these organisms. EIEC strains, unlike most *E. coli* strains, are lysine decarboxylate negative and are nonmotile. Presumptively identified strains must then be confirmed in a reference laboratory by DNA probe or the Sereny (guinea pig eye) test.

STEC diarrhea should be suspected in outbreaks of bloody diarrhea in which the affected patients have little or no fever. The infecting strains can be definitively identified only by demonstrating Sxt 1 and Sxt 2 production or possession of genes encoding for Shiga toxins. EHEC strains can belong to many *E. coli* serotypes (see Table 1), but O157:H7 and O26:H11 are the most common. The clinical laboratory can screen for O157 strains by looking for *E. coli* that fail to ferment sorbitol, confirmed to be LPS type O157 and whose motility can be blocked by antisera to H7.

Multiplex PCR for identification of EPEC (*eae* A, *bfp*), ETEC (ST, LT), EIEC (*ial*) and STEC (stx1, stx2, *eae* A) has shown to be useful for large epidemiological studies.[56,57]

EAEC identification will remain a diagnosed condition only by research laboratories until efficient laboratory reagents are available.

Table 3. Features of Diarrheagenic *E. coli* Infections

	EPEC	ETEC	EIEC	STEC	EAEC
Laboratory diagnosis	Serotyping, DNA hybridization, PCR	ST and LT detection by ELISA, DNA hybridization or PCR	Sereny test, DNA hybridization, PCR	Serotyping or Shiga toxin production by EIA	HEp-2 cell adherence or PCR
Prevalence	Occasional cause of hospitalized diarrhea among infants	Occasional occurrence in United States, causes travelers' diarrhea in 40–60%	Rare	Increasing outbreaks of foodborne dysentery, occasional hemolytic uremic syndrome	Causes persistent pediatric diarrhea in developing regions, occasional cases of acute diarrhea in industrialized areas and AIDS-associated diarrhea
Outbreaks	Nurseries	Travelers, infants, foodborne	Foodborne	Foodborne, less commonly waterborne outbreaks	Foodborne diarrhea outbreaks in developing regions
Geographic	Worldwide, more common in developing countries	Developing nations, occasionally in United States and developed regions	Worldwide, more common in Brazil and in Eastern Europe	Developed countries or countries of the southern hemisphere (Argentina, Chile, South Africa)	Worldwide, more common in developing countries
Temporal	Summer peak	Year-round, summer peak	Unknown	Summer peak	Unknown
Age	<2 years, more common ≤6months	Travelers, children	Unknown	All ages, most common in children	Most common in infants and children

9. Control and Prevention

9.1. General Concepts

Since *E. coli* diarrhea is not a reportable condition, we do not have adequate information about the epidemiology and optimal control and intervention procedures. It is clear that during EPEC outbreaks, standard public health and infection control procedures are important in terminating transmission. Isolation of cases, cohorting by area and nursing personnel, institution of strict hand washing and prevention of common exposure to equipment, bedding or solutions are all indicated.

In ETEC diarrhea of travelers, careful selection of food by individuals and institutions and enforcement of food hygiene in public eating establishments by departments of public health are the major areas for disease control. In high-risk areas, ingestion of steaming foods and beverages, carbonated bottled drinks and citrus fruits and avoidance of moist foods maintained at room temperature (e.g., leafy green vegetables, cold meats, desserts, fresh cheese and milk) are advisable when traveling in parts of the world where food sanitation is substandard. While consumption of tap water in the developing world is not advisable, using this water for rinsing the mouth and toothbrush is generally safe.

In EIEC diarrhea, it is not known whether person-to-person spread occurs but considering the relatively large inoculum responsible for disease, it is likely that food or less commonly water represent the important vehicles of transmission. No specific information on the control of EIEC is available.

STEC infection is best prevented by avoidance of undercooked beef, especially hamburger, monitoring of other foods including produce and adequate chlorination of water to which persons are exposed.

There are no known principles of prevention of EAEC diarrhea other than avoiding consumption of contaminated food which may be possible for travelers by eating only steaming hot foods.

9.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis

The most important factor in treatment of any diarrheal disease is the maintenance of fluid and electrolyte balance by administering oral rehydration fluids. The value of antimicrobial agents in the control of hospital outbreaks of EPEC diarrhea has not been established.

Antibacterial drugs will significantly shorten the duration of ETEC diarrhea and EAEC diarrhea as studied in travelers during short-term stay in endemic areas. The antimicrobial drugs of value include rifaximin,[83] the fluoroquinolones[84] and azithromycin.[84] In studies of ETEC and EAEC diarrhea, a variety of antimicrobial agents have been used with success in preventing illness among travelers from low-risk to high-risk areas. The most active drugs are the fluoroquinolones and non-absorbed (<0.4%) rifaximin. Of these only rifaximin can be recommended for general use as a chemoprophylactic agent, based on efficacy, safety and minimal concern about development of resistance for a non-absorbed drug.[85] Rifaximin may be recommended for diarrhea prevention among travelers to high-risk areas for those on a tight schedule, when illness has occurred during past trips (suggesting increased susceptibility) and when it is requested by the future traveler.[86] A fourth group in which to consider use of rifaximin prophylaxis is the group with immunosuppression or where the underlying illness could predispose to complications if diarrhea developed. It is likely that rifaximin would also prevent EIEC diarrhea in high-risk settings.

In STEC infection, antibiotics have not been clearly demonstrated to be of value. Certain antibacterial drugs may lead to increased production of Shiga toxin and potentially encourage the development of the hemolytic uremic syndrome (HUS).

9.3. Immunization

No immunizing agents are available for EPEC, EIEC or EHEC infections.

Efforts are currently under way to develop a vaccine against ETEC. The impetus for this is two-fold. First, ETEC strains are major and predictable causes of diarrhea in international travelers, the military and state department employees traveling to developing regions and among children living in these areas. Second, ETEC immunity occurs naturally. In an ETEC-endemic area a longitudinal study of protection from natural ETEC infections in children revealed that ETEC infections produced 47% protection against new infections with strains of ETEC showing the same toxin CFA profile.[87] The authors provided evidence that for breastfed children living in endemic areas other antigens are substantially more important than CFAs for induction of ETEC-protective immunity. An orally administered cholera vaccine made of killed ETEC whole cells (expressing CFAI, II and IV) and the binding subunit of cholera toxin is currently available in some areas of the world for prevention of ETEC diarrhea.[88] In the published studies, short-term protective efficacy was particularly impressive for LT-ETEC diarrhea causing life-threatening dehydration; however, protection against ST-ETEC strains was not evident. Heat-labile enterotoxin (LT) applied as a transcutaneous antigen has been shown to be immunogenic.[89] The LT patch vaccine effectively prevented moderate to severe travellers' diarrhoea in a phase II clinical trial.[90] The approach is currently being pursued for commercial development as an immunizing agent for travelers and other high-risk populations.

10. Unresolved Problems

In tEPEC disease, the most important issue to be resolved is the current importance of this group of organisms which are rarely studied today. Regarding aEPEC, studies are needed to determine if these organisms are human pathogens and if so how often they produce enteric disease and in which populations.

In ETEC diarrhea, the most pressing problems center around the development of assays to efficiently identify ST, LT and CFAs in the routine diagnostic laboratory and successful development of protective immunoprophylactic agents.

The prevalence, epidemiology and improved diagnosis of EIEC diarrhea are needed to be clarified further.

Much needs to be learned concerning the prevalence, epidemiology, pathogenic mechanisms, detection and immune response to Shiga toxin-producing *E. coli*. Important questions relate to the exact relationship of EHEC infection to the development of HUS and the role of antimicrobial agents in disease pathogenesis and therapy.

Diarrheagenic *E. coli* comprise a diverse group of strains that should be classified by the pathogenic mechanisms they possess. Improved definitions of diarrheagenic *E. coli* should be given priority.

CHAPTER 16

Gonococcal Infections

Jonathan M. Zenilman and J. McLeod Griffiss

1. Introduction

Despite currently effective means of diagnosis and treatment, gonorrhea remains a major public health problem throughout the world. In 2005, 339,593 cases of gonorrhea were reported to the Centers for Disease Control by local and state health departments, [1] representing a nationwide population-based incidence case rate of 115/100,000. From 1975 through 1997, the national gonorrhea rate declined 74.3% following implementation of the national gonorrhea control program in the mid-1970s. Gonorrhea rates subsequently appeared to plateau for several years; however, the gonorrhea rate has decreased 11.8% from 2000 to 2004. An additional one to two cases are thought to occur for every reported case.[2] The highest rates are seen in adolescent women (aged 15–19 years) and young adult men (aged 20–24 years) representing, in part, sexual behavior patterns. *Neisseria gonorrhoeae* is a major cause of pelvic inflammatory disease,[3,4] which in turn causes tubal factor infertility and ectopic pregnancy. Gonococcal infection also facilitates human immunodeficiency virus (HIV) transmission.

The epidemiology of gonorrhea is determined by the complex interaction of human sexual behavior, social and health-related factors, and the biological characteristics of the organism. Prevention and control of gonococcal infection depend on individual and community education, high standards of diagnosis and treatment, appropriately targeted screening, counseling, and contact tracing.

Jonathan M. Zenilman • Professor of Medicine, Chief, Infectious Diseases Division, Johns Hopkins Bayview Medical Center, 4940 Easter Avenue B-3 North, Baltimore, MD 21224. Infectious Diseases Division, Johns Hopkins Bayview Medical Center, Baltimore, Mayland 21224, USA.

2. Historical Background

Allusions to gonococcal infection may be found in ancient Assyrian and Chinese writing, as well as in the Book of Leviticus (15:2). Relatively clear clinical descriptions were made by Hippocrates and Galen, who mistook the inflammatory discharge (leukorrhea) for semen—hence, "gonorrhea" or a "flowing of seeds". Between the 14th and 17th centuries, "gonorrhea" was considered by many to be just another manifestation of syphilis. However, Phillipe Ricord showed that it was a unique, transmissible disease by performing a series of inoculation studies in the 1830s, and Albert L.S. Neisser reported from Breslau (Wroclaw) in 1879 that he had observed "micrococcenform" in secretions from patients with gonorrhea with the use of stains and a Zeiss microscope outfitted with a newly developed condenser and oil-immersion system.[5] The organism was cultured by Bumm in 1885.

Early treatments of gonorrhea consisted of either ineffective oral preparations or potentially dangerous and caustic intraurethral injections. Urethral strictures and secondary infections were common, both as complications of the disease and/or of therapy. The first advance in treatment was reported in 1881 by Carl Credé, in Leipzig, who noted that ophthalmia neonatorum occurred only in infants born of mothers with vaginal discharge; he reduced the rate of this ophthalmic complication of gonococcal infection of the birth canal from $>13\%$ to 0 by instilling silver nitrate drops in the eyes of newborns at the time of birth.[6] Topical treatment at birth remains a mainstay in preventing this infection. The second major advance was the discovery of penicillin in the 1940s, which provided the first hope that gonorrhea could be eradicated. Despite some initial success, the 1960s saw a precipitous 12-year rise in gonorrhea incidence worldwide.[7] At the same time, relative resistance to penicillin gradually increased. In 1976, the introduction of plasmid-mediated

A.S. Evans, P.S. Brachman (eds.), *Bacterial Infections of Humans*, DOI 10.1007/978-0-387-09843-2_16,
© Springer Science+Business Media, LLC 2009

β-lactamase-producing strains foreshadowed an end to penicillin's role as the treatment of choice.[8] Widespread resistance to penicillins and tetracyclines since the 1980s has led to a reliance on newer agents, such as third-generation cephalosporins and quinolones.

The last two decades have witnessed a tremendous expansion in our understanding of the gonococcus and the human response to infection. However, despite this expanding understanding, how best to formulate a successful vaccine remains unclear. At the beginning of the 21st century, the incidence of gonorrhea is more likely to be changed by time-tested public health measures than by advances in molecular biology.

3. Methodology

3.1. Sources of Mortality Data

Fatalities from acute gonococcal infection are rare events, usually resulting from endocarditis or meningitis complicating disseminated gonococcal infection (DGI).[9] Data on mortality from the sequelae of gonococcal infection, such as pelvic inflammatory disease (PID) and ectopic pregnancy, are unreliable because the conditions listed on death certificates are rarely specifically linked to the infection. For example, one study estimated the mortality from PID (all causes) to be 0.29 deaths per 100,000 women aged 15–44 years.[10] However, because the underlying microbial etiology is not listed, determining how many of these were related to gonococcal PID is impossible.

3.2. Sources of Morbidity Data

Gonorrhea is a reportable disease in all 50 states. Reporting criteria are based on standardized surveillance definitions that may be clinically or laboratory based.[11] Physicians, laboratories, and institutions have been required to report either positive diagnostic test results or the diagnosis, name, address, demographic data, and identity of the reporter to local or state health departments, depending on the jurisdiction. Despite these requirements, there is marked underreporting; an estimated 50–70% of cases are not brought to the attention of local public health authorities.

Data on all reportable infectious diseases, including sexually transmitted diseases (STDs), are reported by the states to the federal Centers for Disease Control and Prevention (CDC). The weekly incidence of gonorrhea is reviewed in the CDC publication *Morbidity and Mortality Weekly Report*. National statistical summaries of STD data are published annually.[1] In addition, antibiotic resistance surveillance is conducted through a variety of mechanisms. The United States and other countries (e.g., Canada and Australia) monitor antibiotic resistance through gonococcal isolate surveillance projects which assess periodically collected samples of gonococcal isolates.[12,13]

In the US military, gonorrhea and other STD reporting is a function of the Prevention Medicine Units (PMU) or infectious disease units for each of the armed services. Military bases located in the United States usually coordinate reporting and disease intervention activities with local county or state health departments. Bases located overseas report STD morbidity to the appropriate Preventive Medicine Command through the PMUs.[14]

Outside the United States, reporting requirements vary. Most countries do not have national-based surveillance for gonorrhea. The areas with the most complete reporting of gonococcal disease are Great Britain and the Scandinavian countries.[15,16] Data from other countries may rely on reports from STD clinics alone. For a case to be included in the national morbidity statistics, it first must be diagnosed, then reported, and finally correctly tabulated. Misdiagnosis, underdiagnosis, and underreporting probably occur frequently. The extent of these errors, or reporting bias, is partially determined and corrected by special surveys. Interpretation of disease incidence data must be carefully done, taking into account possible confounding factors, such as reporting bias, demographic trends, underreporting, and sexual behavior.

3.3. Surveys

Traditional morbidity reporting schemes are often biased because of substantial private sector underreporting. The development of new, easily fielded nucleic acid diagnostic testing has greatly facilitated and expanded the capacity to perform population-based field surveys to assess gonorrhea prevalence. For example, a large nationally representative survey of adolescent high school students (Add Health) found that a prevalence estimate of gonococcal infection was 0.4% (or 4 per 1,000 persons) among young adults aged 18–26 years.[17] The highest prevalence was in the South at 0.6%, reflecting a historical pattern that has been observed for >50 years. The prevalence among men and women was the same (0.4%). The prevalence of gonococcal infection was substantially higher among African-American men (2.4%) and women (1.9%), as compared to whites (0.1% in both men and women). In a population-based survey in Baltimore, the estimated prevalence was considerably higher than most other population-based estimates.[18] Overall, the prevalence was 5.3% among adults aged 18–35 years.

Among African-American women, the prevalence was 9.3% and among African-American men, the prevalence was 5.3%. The prevalence was 1.3% in both men and women for whites.

Screening has been especially useful in identifying asymptomatic infection in specific populations at high risk for gonococcal infection. Large-scale screening of US military recruits at induction found prevalence rates of 0.6% in men[19] and 5% in women.[20] Persons incarcerated at short-term detention facilities are at high risk for STDs; in Baltimore, the prevalence for gonorrhea is 3.4%.[21] Studies in emergency departments in urban areas such as Baltimore have found asymptomatic gonorrhea prevalence rates as high as 5.3%.[22]

Screening programs and surveys have served multiple purposes in guiding the emphasis of national and state control programs. For example, the National Gonorrhea Screening Program, which started in 1972, provides federal support to the states for gonococcal diagnostic testing and has been instrumental in identifying large numbers of asymptomatically infected women.

Demographic surveys have indicated that persons infected with gonorrhea are geographically concentrated and that targeting intervention efforts in these areas may be productive. An interesting use of reported case data for gonorrhea is the spatial representation of cases using geographic information systems (GIS). To assess the distribution of cases in a city or county, the addresses of gonorrhea cases, their partners, or the venues where partners were met are "geocoded", or placed on a map using coordinates. The cases are then aggregated to a larger geographical unit, such as the zip code or census block. The distribution of disease can then be represented as case counts, case density (number of cases over the area), or incidence rate (number of cases over the number of persons living in the area). Application of these techniques in many urban areas such as Baltimore, Seattle, and Colorado has provided[23–25] useful information regarding the core areas of gonorrhea transmission. Such information can be used to target interventions to specific areas with high incidence of disease (see Section 9.2).

Microbiological surveys, such as the national Gonococcal Isolate Surveillance Project,[12] which started in 1986, have been useful in determining the prevalence of gonococcal strains with antimicrobial resistance. These data, in turn, may be useful in developing recommendations for therapy.

3.4. Laboratory Diagnosis

3.4.1. Isolation of the Organism. Culture of clinical specimens for the organism requires supplemented agar media, such as "chocolate agar", which contains hemolyzed sheep's blood. Since genital sites are not sterile, in order to prevent overgrowth of contaminating microorganisms, selective media, such as modified Thayer–Martin or Martin–Lewis media, are used.[26] These media contain antibiotics (e.g., vancomycin, colistin, and nystatin) that suppress fungi, gram-negative rods, and gram-positive bacteria. However, a very small proportion of gonococci are hypersusceptible to vancomycin and may fail to grow on selective media.

Presumptive identification may be made on the basis of growth on selected media, characteristic colonial and microbial morphology, and a positive oxidase test. The gonococcus lacks the enzymes maltase, sucrase, and lactase that split glucose from complex disaccharides; it can metabolize glucose, but not maltose, sucrose, or lactose, and this pattern of use distinguishes it from other *Neisseria*. Final identification may be confirmed by immunologic or molecular biology techniques. A variety of immunologic confirmatory tests, such as direct fluorescent polyclonal or monoclonal antibody stains, are commercially available.

Specificity of culture without confirmation varies by anatomical site and the concomitant presence of commensal organisms that could produce false-positive results. Specificity of presumptive laboratory diagnosis of urethral cultures (i.e., identification without confirmation by sugar use or monoclonal antibodies) in men is over 95%. For cervical specimens in women, specificity is around 85%.[27] In pharyngeal, rectal, and ocular infections, the specificity is lower and all isolates from these and other unusual sites should be confirmed. *All* isolates from children and others in whom sexual abuse or assault is a consideration should be confirmed and saved.

In practice, cultures should be obtained from the anatomical sites corresponding to the patient's sexual exposures by history. Pharyngeal and rectal cultures should be performed if indicated. Because up to 30% of women have rectal coinfection with cervical gonorrhea (irrespective of history of rectal intercourse), routine rectal culture is recommended for all women.

Compared to nucleic acid amplification tests, estimates of culture sensitivity are 90–95% for urethral cultures in symptomatic men and 50–80% for asymptomatic male urethral or cervical infection.[28,11] Rectal cultures probably have a sensitivity similar to cervical cultures. Therefore, either site may be the sole site where infection can be detected. Pharyngeal culture sensitivity is probably somewhat less. In all cases, specificity should approach 100% if confirmatory procedures are used.

Laboratory diagnosis of gonococcal infection from normally sterile sites, such as blood, synovial fluid, cerebrospinal fluid (CSF), and conjunctivae, is often challenging.

In these cases, the selective media used for genital cultures should not be used. Blood and synovial fluid should be cultured on enriched broth media. Synovial fluid, conjunctival discharge, and CSF should be plated directly onto supplemented chocolate agar and placed in a CO_2 incubator as soon as possible. Gram's stain of conjunctival discharge, joint fluid, and CSF may be a useful adjunct.

In gonococcal septicemia (disseminated gonococcal infection—DGI), sensitivity of blood culture, under the best conditions, is often less than 50%. However, the presence of positive blood cultures often correlates with the type of DGI syndrome. For example, in cases of dermatitis and/or synovitis (without frank arthritis), half of the patients have documented bacteremia.

Gram's stains of urethral and cervical exudates should be performed when specimens for culture are obtained. In men, demonstration of typical gram-negative diplococci within polymorphonuclear leukocytes in a urethral smear is 95% sensitive and almost 100% specific.[29] In women, sensitivity of cervical smears is only a little better than 50%, although specificity is 95%. Gram's stains from rectal and pharyngeal sites are not recommended because of low sensitivity and specificity.

Susceptibility testing is not routinely performed. However, direct susceptibility testing using either the disk diffusion method or E-test diffusion testing should be performed on all isolates where initial treatment failure can result in severe sequelae (e.g., DGI, endocarditis, ophthalmia, and invasive soft-tissue infections).

3.4.2. Immunologic and Molecular Diagnostic Methods. Since the late 1980s, there has been a trend toward the use of nonculture methods. These methods offer practical and logistical advantages, such as simple specimen transport, but are expensive and must be done in a CLIA (Comprehensive Laboratory Improvement Act)-certified laboratory.

Leukocyte esterase dipsticks were initially evaluated as a cheap, initial screening test for gonorrhea. The poor sensitivity of the test (40–70%) has limited its clinical value.[30] However, it may be useful in low (<5%) prevalence settings where its high negative predictive value (93–98%) can be used to identify clients who should be assessed with culture and/or confirmatory testing, thereby focusing diagnostic resources where they will yield the highest return.[31]

Nucleic acid hybridization tests, which detect *N. gonorrhoeae*-specific DNA or RNA sequences, were developed in the early 1990s.[32] However, the relatively low sensitivity of direct hybridization tests, as compared with culture (approximately 85%, depending on site), limits their usefulness, and they largely have been replaced by nucleic acid amplification tests (NAATs). Direct hybridization tests remain useful for confirmation of culture results and/or NAAT results.

NAATs that are currently cleared for diagnostic use by the Food and Drug Administration rely on polymerase chain reaction, ligase chain reaction, strand displacement amplification, or transformation-mediated amplification.[11,33,34] The sensitivity and specificity of a NAAT depends on the nucleic acid sequence that is being amplified, the genetic characteristics of prevalent strains, which will vary over time and among different networks of people who practice unsafe sex (molecular epidemiology), and the prevalence of commensal *Neisseria* that may have acquired gonococcal nucleic acid sequences by lateral transfer, which is common among *Neisseria.*[35] In settings in which the prevalent gonococcal strains can be detected by a NAAT, sensitivities usually are greater than culture, particularly for endocervical sites, and approach 100%. Because of the high sensitivity of the DNA amplification process, these tests can be used on urine from either men or women.

Testing of oropharyngeal and rectal specimens with NAATs is not recommended because of high prevalences of pharyngeal carriage of nongonococcal *Neisseria* and interference by nucleic acid from enteric bacteria. The sensitivity and specificity of NAATs can be improved by the use of two different NAATs or by confirmation with a direct hybridization test, but this increases the cost. Efficiency can be gained by pooling urine specimens, particularly in low-prevalence settings.

4. Biological Characteristics of the Organism

N. gonorrhoeae is a fastidious aerobic and facultatively anaerobic gram-negative diplococcus that grows best at 35–36°C on a rich medium (such as chocolate agar) containing hemoglobin and a variety of other nutrients, in a moist atmosphere containing at least 3% CO_2. Characteristic colonies are small, rounded, and glistening gray after 24 hours of incubation and are nonhemolytic on blood agar.

In the early 1960s, a relationship between gonococcal colonial morphology and virulence was established. Sharply bordered colonies, which contain organisms with pili, caused urethritis when instilled into the distal urethrae of male volunteers, whereas diffuse colonies, formed by organisms without pili, were unable to cause disease following intraurethral challenge.[36] Non-piliated gonococci also are unable to invade cultured human genital epithelial cells.[37,38] Pili are thin, proteinaceous hair-like fimbriae that extend from the cell wall and enable gonococcal adherence to the epithelial cells of mucosal surfaces. Besides pilin,

the gonococcal cell membrane contains lipooligosaccharides (LOS) and three integral major outer membrane proteins (OMP).[39]

LOS are triantennary OM glycolipids that share structural organization and oligosaccharides with human glycosphingolipids (GSL).[40–42] They have oligosaccharides of three glycoform series (Table 1)—globosyl, paraglobosyl, and gangliosyl—that are linked to basal lactose disaccharides, designated Lc_2, and that extend from either or both of the basal region heptose (Hep) residues, designated Hep1 and Hep2. Hep1 is linked to Kdo; Hep2 to Hep1. The glycoform series are identical to those of the analogous GSL series.[43–45]

The organism must express paraglobosyl LOS in order to cause disease.[46] LOS have endotoxin activity similar to that of the lipopolysaccharides (LPS) found in the walls of enteric gram-negative bacteria. Gonococcal LOS induce apoptosis of ciliated human fallopian tube epithelial cells through the induction and secretion of tumor necrosis factor-α by adjacent non-ciliated epithelial cells to which the organisms bind and on which they form microcolonies.[47] The non-ciliated cells are protected from apoptosis by abundant intracellular galectin-3, a human lectin that binds β-galactose molecules that terminate LOS oligosaccharides and disrupts apoptotic pathways.[48] The loss of ciliated epithelial cells results in scarring of the fallopian tube and infertility.

Protein I, the major gonococcal OMP, consists of two porins, designated PorA and PorB, that form voltage-dependent aqueous channels that allow the selective passage of solutes through the hydrophobic outer membrane.[49] A variety of serologically distinct forms of protein I exist and are genetically stable over time. This stability has allowed the development of a monoclonal antibody-based serological typing system.[50,51]

Protein II, or opacity-associated protein (Opa), is involved in gonococcal adhesion to mucosal surfaces. The antigenic diversity and rapid antigenic variation of Opa may allow the gonococcus to escape from the immune system.[52] Protein II is closely associated with protein I in the cell membrane. The precise function of protein III is unknown, but the presence of antibodies directed against protein III may increase the risk of gonococcal infection.[53]

N. gonorrhoeae must scavenge environmental iron in order to survive and replicate.[54] Gonococci that are recovered during menses are more likely to have their phase variable hemoglobin receptor in the "on" phase than those isolated later during the cycle.[55] Most bacteria acquire iron from the environment by excreting siderophores. Gonococci, however, use a unique iron capture system by which cell surface proteins remove iron directly from human iron-binding proteins, such as lactoferrin and transferrin. This ability to steal iron from the host's iron-sequestering system is an essential factor in gonococcal pathogenesis. Gonococci are most likely to be recovered from the uterine cervix just before and during menstruation (days –2 to 5),[56,57] when hemoglobin iron is abundant.[58] Gonococcal mutants that do not express the transferrin receptor are unable to infect the male urethra.[59]

5. Descriptive Epidemiology

Useful data on the trends of reported cases of gonococcal infection are available in countries where most cases are seen in public specialized clinics (United Kingdom), where most laboratory tests are performed in a single central laboratory (Denmark), or where few changes in reporting habits have occurred (United States). In developing countries, accurate assessments of gonorrhea and other STI incidence and prevalence largely do not exist.

5.1. Prevalence and Incidence

The reported cases of uncomplicated gonococcal infection in the United States are depicted in Figure 1. The total number of reported cases peaked in 1978, with 1,013,436, and has since decreased to 330,132 in 2004. Changes in cases

Table 1. LOS Oligosaccharide Glycoform Series

reported among women reflect not only cases presenting for treatment but also additional case-finding by screening. Trends in acute gonococcal urethritis in men are less influenced by efforts of health workers to find cases.

Despite the decrease in the number of reported cases of gonorrhea, there has been only a minimal change since 1998 in the rate of gonococcal infections among the highest risk age groups (15–44 years old), especially in urban areas. Since the late 1990s, gonorrhea rates in homosexual men have increased dramatically,[60,61] which is especially troubling, and is part of a general trend of "behavioral disinhibition" in this risk group. These trends contrast with the sharp decrease of rectal gonorrhea in the early 1980s, representing a response to safer sex messages of the early HIV epidemic.[62]

Reported cases help define trends, but they largely represent symptomatic cases seen in public health clinics. Population-based surveys, such as those described above in Section 3.3, have defined that standard surveillance data underreport disease incidence by at least 70%.[17,63]

Serious forms of gonococcal infection, such as ophthalmia, acute and recurrent salpingitis, epididymitis, and DGI, have not been systematically recorded even in those countries, such as the United Kingdom and Scandinavia, where centralized registries are available.

5.2. Epidemic Behavior and Contagiousness

The spread of gonorrhea in a community is related not only to sexual behavior and the risk of transmission of the disease on exposure, but also to the natural course of the disease, the health behavior of infected individuals, and health care access and available resources.

Figure 2 shows the relationship of incubation period, symptoms, and transmission rates to the spread of gonorrhea; it should be useful in correcting several myths about the spread of this disease. It is incorrect to assume that all men with urethral gonorrhea develop typical acute urethritis,[18,64,65] that the vast majority of women with gonorrhea have no symptoms, or that the cycle of transmission goes from asymptomatic women to symptomatic men and back again. Tracing the course of gonorrhea in Figure 2 will illustrate these points. Begin with uninfected women being exposed to infected men: the majority of men who infect women have no or very early urethral symptoms. The effectiveness of male-to-female transmission is high. At least 50% of women will be infected during a single episode of vaginal intercourse with an infected man; risk increases to over 80% with multiple exposures to the same infected partner.[66,67] As is the case with men, women increase their risk of infection by having sex with multiple partners. Once infected, many women will develop either acute salpingitis (20–40%) or a constellation of less-specific symptoms (20–30%) (e.g., dysuria, perineal syndrome, vaginal discharge and/or odor, abnormal uterine bleeding) within 3–45 days of infection.[68,69] The remaining 30–60% of infected women will have minimal or no symptoms, yet will carry the gonococcus endocervically for 3–12 months.

Next, consider the uninfected men shown in the lower right corner of Figure 2 who will be exposed mainly to women who are unaware of symptoms; transmission of gonorrhea occurs 20–25% of the time.[70,71] Although the majority of men with urethral infection develop frank urethritis (80%), some have atypical signs and symptoms (15–18%). The tendency to seek treatment for either typical or atypical presentations of gonorrhea will vary among different social and psychological groups, so that the perceived incubation period may well vary from 2 to 30 days, if the patient seeks medical advice at all. Some asymptomatic urethral carriers may be of long duration (2–5%) and are very important vectors of gonorrhea; thus, the cycle repeats itself.

Most gonococcal infections are transmitted from asymptomatic individuals or from those who do not recognize atypical signs and symptoms of the disease. This is true for both sexes. Thus, both men and women who seek care for acute symptomatic urethritis or symptomatic pelvic infection will in all but rare cases have acquired their infection from infected sexual partners who have no symptoms. Last, infected women frequently have symptoms that are nonspecific, and some men have no symptoms. These asymptomatic men accumulate in high-risk populations and may be major contributors to the spread of disease in the community.

Homosexual men can develop symptomatic proctitis with anorectal infection, but the majority are asymptomatic. The course of urethral infection in gay men is similar to that in heterosexual men. Pharyngeal gonococcal infection is usually asymptomatic in both sexes[72] and, although quite common among gay men, is an unlikely but possible source of disease transmission.

5.3. Geographic Distribution

Reported case rates of gonorrhea vary widely among the states. These variations may reflect population factors, such as socioeconomic status, as well as differences in local control programs, such as case-finding activity, reporting practices, and the availability of public clinics.

The highest gonorrhea rates in the United States occurred in the Southeast. Large cities generally had significantly higher rates than suburban and rural communities, although gonorrhea rates in some rural areas, especially the

South, can be deceptive—although case counts may be relatively low, because of a small denominator population, rates can exceed those of the large urban areas.[73]

Although the gonorrhea rates determined for large populations are helpful in delineating trends, the "core group" theory may be more valuable for directing control efforts.[24,74] Gonorrhea rates appear to be extremely high in geographically localized, small populations participating in high-risk behavior.[24,74,75] Inner-city areas with low socioeconomic status and poor health care access are most severely affected. For example, out of a total of 202 census tracts in Baltimore, 12 census tracts located in the inner city (core) accounted for 50% of reported gonorrhea morbidity[76,77] (Figure 3). Within these census tracts, the gonorrhea rate is estimated to be five to six times higher than the overall citywide rate. Control efforts focused on core groups would potentially have the most cost-effective impact on overall gonorrhea rates.

5.4. Temporal Distribution

A marked seasonality of reported cases has been found ever since data began to be collected in the United States. Consistently, the incidence of reported disease is at least 20% higher in August through October than in February through May. The seasonality of reported gonorrhea cases may reflect combinations of greater mobility, leisure time, and sexual activities in summer. However, probably more important is the increased use of antimicrobials for upper respiratory infections during winter, which has the collateral effect of treating asymptomatic gonococcal and chlamydial infections.[78,79]

5.5. Age and Sex

Young adults and adolescents are at the greatest risk of acquiring gonorrhea. The high rates in these age groups may be secondary to increased risk-taking behavior and to physiological factors, such as increased cervical ectopy in adolescent women. During the last decade, the age group with the highest rate of gonorrhea has become progressively younger. Currently, teenage females (15–19 years of age) have the highest rate of gonorrhea. Although young adult males (20–24 years of age) have a higher rate than teenage males (15–19 years of age), the difference between these two groups has decreased markedly since 1987.

5.6. Race

Although the reported cases of gonorrhea in all ethnic groups have been decreasing since 1986, the rate of gonorrhea among African-Americans has increased 100-fold than in other ethnic groups. There is no reason to suspect an increased biological susceptibility. Traditional explanations have included lack of health care access among racial minorities and increased use of public sector clinics, which are more likely to report cases than the private sector. However, large prospective prevalence studies which have adjusted for class[17,18] clearly indicate that the racial disparity is real. Furthermore, carefully performed studies from London and Leeds in the United Kingdom, which controlled for social class and where health care access is universal, demonstrated similar consistent patterns, where Blacks of Caribbean or African backgrounds had gonorrhea rates >10 times that of whites.[80,81] The risk profile of individual patients in these studies does not differ greatly between the gonorrhea-impacted and non-impacted groups. These patterns are also seen with other STDs with wide distribution such as herpes and chlamydia.

One approach toward explaining this phenomenon has been the concept of social networks.[82,83] In the social approach, the risk profile of the *partners* is as important or even more important than the risk for the index case. Using large national datasets, social science researchers have consistently shown that African-Americans with gonorrhea are more likely to have sexual partners which are *dissociative*(i.e., different in social class and behaviors) than other groups and are more likely to have closer social/sexual network connectivity with persons at higher risk for STDs such as gonorrhea.[84–86]

5.7. Occupational and Socioeconomic Factors

Commercial sex workers are at considerably higher risk[87,88] than the general population. Gonorrhea rates of 5–10% are seen frequently in incarcerated prostitute populations. In developing countries, gonorrhea and other STDs are often associated with occupational classes that afford mobility and access to sex workers. Specific high-risk situations include truck drivers[89,90] and workers who are separated from their spouses or regular partners for long periods of time, such as migrant workers or South African gold miners. In these latter situations, there is often opportunity for development of a commercial sex industry.

5.8. Homosexuality

Rectal gonorrhea is used by public health authorities as a sentinel infection for risk behavior in homosexual men. STDs in gay men reflect social changes and societal attitudes. Gonorrhea in gay men increased dramatically in the late 1970s, concordant with the gay liberation movement,[91] and

decreased rapidly during 1981–1984 secondary to behavioral changes in the face of the AIDS epidemic.[62] Unfortunately, since 1998, there has been a resurgence which has been observed both in the United States and in Western Europe.[60,61] Hypotheses for this trend include "prevention fatigue" among gay men who have been practicing safer sex for >20 years, a rebellion of a younger generation of gay men against the safer sex peer norms of the "older" generation. However, the most likely hypothesis of this behavioral disinhibition phenomenon is the development of effective antiretroviral therapy, which has made HIV evolve from a fatal infection of short duration to a chronic, manageable disease.

5.9. Gonorrhea and HIV

Gonorrhea and other STDs facilitate HIV transmission. A Baltimore case–control study of HIV seroconverters found a 3-fold increased risk in patients who had a diagnosis of gonorrhea at their last STD clinic visit prior to seroconversion.[92] Prospective studies in India[93] and Zaire[94] conclusively demonstrated an association between exudative STD and HIV seroconversion. In the Zaire study, commercial sex workers with chlamydia had a 4.6 relative risk for seroconversion, for those with gonorrhea, the relative risk was 3.6; both relationships were stable after controlling for other confounding variables. From a population perspective, gonorrhea and chlamydial infection may be more important because they may be associated with a higher attributable fraction of HIV seroconversion cases. For example, the Baltimore investigators, whose population included a large number of intravenous drug users, concluded that the adjusted attributable fraction of HIV seroconversions related to coexistent gonococcal infection was 18%.

5.10. Antimicrobial Resistance

The emergence of plasmid-mediated penicillinase-producing *N. gonorrhoeae* (PPNG) in 1976 quickly ended penicillin's role as the treatment of choice for gonorrhea. Currently, third-generation cephalosporins and fluoroquinolones are considered the drugs of choice. However, the ever-increasing development of resistance among all pathogenic organisms in the face of antimicrobial pressure raises serious doubts about the long-term effectiveness of even these newer agents.

5.10.1. Penicillin and Beta-Lactam Resistance. Resistance to penicillin may be either chromosomally (CMRNG) or plasmid (PPNG) mediated. Chromosomally mediated increases in the minimal inhibitory concentration (MIC) of penicillin were noted during the 1950s and 1960s. By 1979, the recommended dose of penicillin was 200-fold higher than that used after World War II. However, these moderately resistant strains still had MICs < 1 μg/ml and could be successfully treated with penicillin.[95] CMRNG strains with high-level resistance (MIC > 2 μg/ml) were first identified in North Carolina in 1983.[96] Resistance in these strains resulted both from the cumulative effect of multiple genetic mutations leading to altered outer membrane permeability to antibiotics and also from changes in the penicillin-binding proteins. Due to the changes in permeability, CMRNG strains are also frequently resistant to tetracycline and second-generation cephalosporins.

Plasmid-mediated PPNG was introduced into the United States in 1976.[8] In 1992, 11.6% of isolates submitted in a sentinel survey in the United States were PPNG; however, this had decreased to 0.6% in 2004 with the decreased use of penicillin class antibiotics.[1] Interestingly, although occasional cases of cephalosporin-resistant organisms are reported,[97] chromosomally mediated resistance to cephalosporins has been rare during this period despite the increased use of ceftriaxone and similar drugs.

5.10.2. Tetracycline-Resistant Gonorrhea (TRNG). Tetracycline is not used as a sole drug for treating gonorrhea, but is recommended as a cotreatment regimen for chlamydia and is therefore widely used. Tetracycline resistance also may be either chromosomally or plasmid mediated. Plasmid-mediated TRNG strains carry a 25.2 MDa plasmid, which carries the *tetM* gene. This genetic mechanism is of public health interest for two reasons. First, it represents acquisition of a resistance determinant from other genital flora. Second, in vitro studies have been able to transfer *tetM* to other *Neisseria*, including the meningococcus.[98,99]

5.10.3. Fluoroquinolones and Resistance. Fluoroquinolones act by disrupting bacterial DNA synthesis through binding and subsequent inhibition of specific members of the topoisomerase family of enzymes, DNA gyrase and DNA topoisomerase IV,[25] which mediate the uncoiling of DNA during replication.[26,27] Primary mechanisms of resistance in GC are associated with point mutations within the *gyrA* and *parC* genes, which code for the DNA gyrase and topoisomerase IV proteins, respectively.[100–103] Efflux pump mechanisms, which mediate the active transport of quinolones from the organism after absorption, have also been described.

Quinolones were recommended as a single dose, oral therapy for gonorrhea in 1989, and became widely used in the early 1990s. Quinolone-resistant strains (QRNG) were first identified in 1991 and currently represent nearly 20% of isolates in Hawaii and California and among homosexual

men.[104–106] As a result, this class of drugs is rapidly losing its usefulness.

6. Mechanisms and Routes of Transmission

The major mode of transmission of gonococcal infection in adults is through sexual intercourse (see Section 5.2). Nonsexual transmission of gonorrhea is extremely rare among adults and epidemiological data implicating fomites in transmission are lacking. Infants born to infected mothers can acquire conjunctival infection and orogastric colonization before delivery (with premature rupture of fetal membranes) or during delivery. Children up to the age of 5 years rarely acquire the disease from fomites or inoculation with infected adult secretions. Therefore, in all infected children, family situations must be examined closely, because sexual abuse, frequently involving a member of the household, is a far more likely mode of transmission.[107] Most cases of gonorrhea in adolescent children are acquired through sexual intercourse.

7. Pathogenesis and Immunity

7.1. Pathogenesis

N. gonorrhoeae is an obligate parasite of humans that has no other natural host. In the absence of an experimental animal that is naturally susceptible to gonococcal infection investigators have returned repeatedly over the past 100 years to experimental infections of male volunteers for studies of pathogenicity and resistance.[36,108,59,109] Human challenge studies overcome the problem of not being able to reproduce faithfully in organ or tissue culture the complex molecular environment of the male urethra. They have contributed greatly to an understanding of some of the clinical parameters of gonococcal infections in men and of the infectious phenotype(s) of the organism for the male urethra.

7.1.1. Pathogenesis for the Male Urethra. *N. gonorrhoeae* cannot survive outside the human body. The reservoir of infection is within the endocervical epithelial cells of chronically infected women from which organisms are shed intermittently into the overlying mucous blanket,[57,110] where they may encounter the heavily sialylated stratified columnar epithelium of the distal male urethra.[46,111] Following exposure, men develop symptoms of dysuria and urethral discharge after incubation from 1 day to more than 1 month.[112] Most men are symptomatic within 72 hours of infection. During the period between exposure and the onset of dysuria, organisms often cannot be recovered from urine (eclipse phase) and are thought to be within urethral epithelial cells[113] from which they emerge as "infectious units" that are taken up by phagocytes that have been evoked by inflammatory cytokines released from the infected epithelial cells.[114] The release of cytokines causes dysuria, and this symptom usually is followed within a few hours by the advent of a purulent urethral discharge (leukorrhea)[46] that consists of epithelial cells and numerous polymorphonuclear leukocytes (PMN), a relatively few of which contain gonococcal microcolonies of considerable size.

The efficiency of female-to-male transmission is a function, in part, of the number of organisms that are being shed from the partner's cervix at the time of exposure (inoculum effect). It is not known, however, whether men who are exposed during the perimenstrual period are at greater risk of acquiring infection[56] than those exposed during mid-cycle, when gonococci are sparsely shed.

Resistance to infection of the distal male urethra can be overcome by increasing the inoculum in experimental infections, but most women apparently are not shedding an inoculum sufficient to overcome the level of resistance of their partner's distal urethral epithelium at the time of intercourse. The incubation period is a function of the inoculum in experimental infections in men; not surprisingly, smaller inocula take longer to produce an exudative infection than larger ones.[109]

7.1.2. Pathogenesis for the Female Endocervix. Women whose male partners are infected are exposed to a higher gonococcal inoculum than men, and male-to-female transmission of gonococci is two to four times as efficient as female-to-male transmission. Men with gonorrhea ejaculate an average of 7×10^6 (6.9×10^4–6.1×10^7) cfu in their semen.[115] This inoculum is independent of semen volume, unaffected by urination prior to ejaculation, delivered close to the endocervix, and nearly 100 times larger than that encountered by the distal male urethra during vaginal intercourse with an infected partner. The incubation period is hard to define in women, because cervical infections are often asymptomatic.

Productive infection of endocervical epithelial cells involves four distinct and sequential stages: (1) adherence, (2) uptake, (3) intracellular survival, and (4) exocytosis. Each of these uses different bacterial organelles and involves different host cellular response elements.

N. gonorrhoeae shed by infected men at the onset of leukorrhea are piliated, express Opa, and make $nLc_{4–8}$ paraglobosyl LOS molecules.[46,116] All three are needed for efficient infection of cultured genital epithelial cells.[117]

Uptake of gonococci by endocervical cells is "parasite directed" through processes that are remarkably complex.[118] Following stage 1 adherence, mediated by pili, Opa, and

an unidentified complex at the tips of host cell microvilli, the organisms replicate over several hours to form surface microcolonies. During this period, both bacteria and eukaryotic cells activate transcription and surface expression of new ligands and receptors.[119] After 4–6 hours of microcolony formation, during which microvilli adhere to bacteria only at their tips, the microvilli elongate, engage the microcolonies along their full lengths, and pull the cell membrane around the microcolony until it is fully engulfed (stage 2).

The onset of symptoms in men with experimental gonorrhea is heralded by a switch in the Opa phenotype of shed organisms from Opa^- to Opa^+.[46] Individual Opa variants can bind up to four different CEACAM receptors. CEACAM are a family of cellular adhesion molecules that are variously expressed by cells in different tissues. Cells of many tissues express more than one CEACAM; other cells express none. CEACAM-mediated uptake of gonococci by endocervical epithelial cells appears to result in the death of the organism; however, CEACAM-mediated uptake by PMNs may account for the survival of the microorganisms within these phagocytes.[120] Only about a third of women constitutively express CEACAM on their endocervical epithelial cells. Since roughly a third of women resist gonococcal infection after exposure,[70] constitutive CEACAM expression may enable endocervical epithelial cells to resist infection.

The terminal β-gal of nLc_{6-8} LOS molecules is a ligand for two human lectins that have been implicated in gonococcal pathogenesis, the asialoglycoprotein receptor (ASGPR), a C-type lectin, and galectin-3, an S-type (secreted) lectin.[48] Gonococcal adherence to genital epithelial cells causes upregulation of ASGPR expression, but not that of galectin-3. Galectin-3 is a polyfunctional molecule that participates in inflammatory responses and is integral to terminal differentiation processes. Epithelial cells that are invaded by gonococci constitutively express galectin-3. Ligation of galectin-3 by nLc_{6-8} LOS molecules may prevent apoptosis and enable intracellular survival (stage 3).[121,122] Unsubstituted paraglobosyl LOS bind C3b to their terminal galactose[123]; bound C3b then is degraded to iC3b, the primary ligand for the CR3 complement receptor, which is constitutively expressed by endocervical cells. How—and when—in the processes of productive infection the nLc_{4-8} LOS:iC3b:CR3 complex acts remains to be determined.

Endocervical epithelial cells express the lutropin (luteinizing hormone) receptor (LHr). Gonococcal adherence to uterine cells causes the bacteria to express a neo-ligand that engages the LHr after 4–6 hours on the cell surface.[124] This results in the uptake of microcolonies. The mucosal epithelium of the female lower genital tract consists of columnar cells that line the endocervix and squamous cells that line the endocervix and vagina; the latter do not support gonococcal uptake. Unlike the epithelial cells that line the urethra, endocervical epithelial cells do not respond to gonococcal attachment and invasion with the release of inflammatory cytokines.[125,126] The lack of an endocervical cytokine response explains the absence of symptoms in most infected women.

7.1.3. Disseminated Gonococcal Infection (DGI). In over 98% of cases, gonococcal infection is restricted to the mucosal epithelium of the male urethra (local infection) or the female genital tract including the uterus and fallopian tubes (ascending infection). This restriction is accomplished by complement-mediated lysis of serum-sensitive bacteria as they enter the bloodstream. In about 1% of cases, mucosal infection, often asymptomatic, will progress to septicemia, caused by variants of the infecting strain that have altered LOS that do not bind the IgM and IgG antibodies which circulate in most people's serum, and that initiate immune lysis. Patients with defects in terminal complement components are at higher risk for DGI, as well, as they cannot complete the lytic cascade.[127–129]

7.2. Immunity

Antibody responses during uncomplicated cervical infections are modest as compared with those that would be expected during a gram-negative infection of the urinary tract.[125,126] IgG is the predominant Ig isotype in endocervical secretions. IgA is produced locally by the endocervix, is overwhelmingly (>80%) polymeric sIgA, and is equally distributed between its two isotypes. IgG and IgM, on the other hand, originate mainly as serum immunoglobulins that are transudated into the endocervical canal. Gonococcal IgM is present in cervical secretions only during the first 2 weeks after infection; gonococcal sIgA is found reliably in cervical secretions during infection, but its levels decline rapidly with successful treatment and are undetectable 50 days after infection.[130,131] Reinfection occurs only after sIgA levels in cervical secretions have waned. Given the short duration of the IgM and sIgA responses after gonococcal infection and the absence of immunological memory of prior infections, women who are only intermittently exposed to the organism are unlikely to have appreciable levels of either Ig in their cervical secretions at the time of exposure. In contrast with sIgA, gonococcal IgG levels in cervical secretions mirror those in serum, arising 7–10 days after infection and declining slowly thereafter. As a result of their different decay kinetics, IgG predominates over sIgA in endocervical secretions.

Gonococcal serum IgG antibodies are acquired with each infection, so that over time and repeated infections, levels of resistance increase.[132,133]

7.2.1. Protein Antibodies. IgG antibodies that bind pilus and OMP are more abundant in the sera of previously infected individuals, and bind lower molecular weight proteins, than in the sera of never-infected individuals, but such antibodies are found readily in the sera of men and women before, or at the time of, a diagnosis of gonococcal infection. Pili are highly immunogenic, but pilus antibodies, which often are present in the sera of infected individuals at diagnosis, do not prevent infection. A purified pilus vaccine that consistently induced broadly cross-reactive IgG antibodies failed to prevent gonorrhea in a field trial that involved 3,250 volunteers.[134]

The porin proteins do not consistently induce antibodies during infection, but may contribute to protection after repeated exposures.[132]

Opa are highly variable, and the antibody response to them during infection is complex. Opa antibodies are not abundant prior to infection and do not appear to protect against endocervical infections. They may provide some protection against PID, however.[107]

Protein III antibodies may actually increase the risk of infection by interfering with complement-dependent clearance of the organisms.[53]

7.2.2. Lipooligosaccharide (LOS) Antibodies. Increases in LOS antibodies—and induction of new LOS specificities—are readily detected in serum and urine during naturally acquired and experimental gonococcal infections.[46,109,135] Paraglobosyl LOS IgG antibodies, induced during a first experimental infection, are associated with resistance to a subsequent challenge. Paraglobosyl LOS IgG is induced during natural urethral infection of men, but also by colonization by commensal *Neisseria*, including *N. meningitidis*, which also express these LOS molecules.

Paraglobosyl LOS IgG are bactericidal for gonococci isolated from local, mucosal infections; that is, they initiate complement-mediated lysis. Gangliosyl IgM also circulates in most people by early adolescence, and these antibodies also are bactericidal for most strains.

8. Patterns of Host Response

Gonococcal infection may be limited to mucosal surfaces, such as the urethra, cervix, pharynx, eyes, and rectum, or, in a significant proportion of infected women, may ascend along the uterine endometrium to the fallopian tubes (PID) or escape immune lysis, such as in DGI.

8.1. Clinical Features

8.1.1. Urethritis in Men. Dysuria and purulent discharge are the most common symptoms.[111,136,137] Although most men have one or both symptoms within 1 week of infection, 5–10% of cases remain asymptomatic.

The differential diagnosis of urethritis in men is between gonococcal urethritis (GCU) and nongonococcal urethritis (NGU). Although GCU is more frequently associated with purulent discharge and dysuria, the diagnosis cannot be confirmed or excluded by history and physical examination alone. Gonorrhea is diagnosed presumptively by Gram's stain of a urethral smear and confirmed by culture or nucleic acid-based tests (Section 3.4). Coinfection with *Chlamydia trachomatis* is common and occurs in up to 50% of patients in some areas.[138]

Untreated gonococcal urethritis usually resolves within 6 months. Because the vast majority of symptomatic men seek early treatment, there are few current epidemiological data on the long-term sequelae of untreated gonococcal urethritis. In developing countries, where chronic untreated infections still occur, paraurethral and preputial abscesses, fistula formation, and urethral strictures occur frequently. Epididymitis and prostatitis are manifestations of ascending infections in men.

8.1.2. Endocervicitis. In most women with gonococcal cervicitis, purulent endocervical exudates and cervical erythema and edema can be detected by a careful visual speculum examination. Erosive cervicitis usually is present only with *C. trachomatis* coinfection, which is common.[112,139] Infected women may have non-specific complaints, such as increased vaginal discharge, abnormal menses (increased flow or dysmenorrhea), dyspareunia, or dysuria. Patients often do not associate these symptoms with an STD. Labial tenderness and Bartholin's and Skene's gland abscesses are less frequent signs of infection. Fifty percent of women are asymptomatic at presentation. Bimanual examination of the pelvis is mandatory in evaluating women with gonococcal infection. As many as half of women with endocervical gonorrhea may at initial evaluation have upper-tract signs such as adnexal tenderness, if such signs are carefully sought.[3,69,140,141]

Definitive diagnosis of gonococcal cervicitis is made by culture or nucleic acid-based tests. Gram's stain of cervical secretions may be useful in identifying cases at the bedside, but has a sensitivity of only 50–70% (see Section 3.4). Coinfection with other genitourinary pathogens, such as *C. trachomatis* or *Trichomonas vaginalis*, is common. Because of the particularly high proportion of coinfection by *C. trachomatis* and the relatively high cost of diagnosis, treatment regimens must be directed against both pathogens.

8.1.3. Upper Genital Tract Infection and PID. PID is the most important complication of gonorrhea. Ascending infection from the endocervix through the uterine cavity

to the fallopian tubes usually occurs within one to two menstrual cycles in 10–20% of women with untreated or undertreated gonococcal infection.[69,140,141] PID is actually a spectrum of soft-tissue infections, including endometritis and salpingitis. Leakage of infected material can result in tubo-ovarian abscess and/or pelvic peritonitis. Apoptotic loss of ciliated tubal epithelial cells impairs ciliary motility, setting the stage for superinfection with vaginal flora and secondary abscess formation. Tubal scarring, the major long-term sequelae of PID, leads to increased susceptibility to repeated episodes of PID as well as to an increased incidence of tubal infertility and ectopic pregnancy.[142]

Patients at highest risk for developing PID are under 25 years old, have had previous episodes of PID, have multiple sexual partners, and douche. Use of oral contraceptives as a risk factor for PID is still a subject of considerable debate.

Clinical diagnosis of PID traditionally has been made on the basis of the triad of lower abdominal pain, abnormal cervical or vaginal discharge, and tenderness on bimanual examination. Fever occurs in only half the cases. Women with PID may have crampy, dull, lower abdominal pain occurring with menses or irregular menses over several cycles before the disease becomes overt. On bimanual examination, the signs of PID are uterine traction tenderness, adnexal tenderness, or adnexal enlargement. Although adnexal abscesses are unusual in gonococcal PID, clinical suspicion should lead to further evaluation, such as sonography. The wide spectrum of disease, including mild cases, and the relative non-specificity of clinical signs make accurate diagnosis difficult. Laparoscopic studies have demonstrated clinicopathological correlation in only two thirds of cases. Therefore, careful clinical observation of the patient is extremely important.

Because of the diagnostic problems and the profound sequelae of untreated or undertreated disease, the CDC and other authorities recommend an aggressive approach to PID diagnosis and treatment.[140] Treatment regimens for PID are designed to include adequate antimicrobial coverage for *N. gonorrhoeae*, *C. trachomatis*, gram-negative organisms, and anaerobes.[143] Hospitalization may be necessary in severe cases. In addition, if foreign bodies, such as IUDs, are present, they should be removed.

8.1.4. Anorectal Infections. Anorectal gonorrhea occurs in homosexual men with a history of receptive rectal intercourse.[144,145] A small proportion of women with endocervical gonorrhea have coexistent rectal infection.[144] In women, anorectal gonorrhea can occur even in women who have not had rectal intercourse. In these cases, infected perineal secretions are thought to secondarily infect the anorectal mucosa.

Most anorectal infections in women are asymptomatic. In homosexual men, symptoms such as tenesmus, mucoid discharge, hematochezia, perianal irritation, and constipation are seen more frequently. Anoscopy in symptomatic cases may show erythema, exudates, and friable mucosa in the anal canal and terminal rectum. In asymptomatic cases, however, anoscopy is often normal. The differential diagnosis of anorectal gonorrhea, especially in homosexual men, includes rectal herpes and *C. trachomatis*. Diagnosis is most accurately made by culture.

8.1.5. Pharyngeal Infection. Pharyngeal infection usually results from oral sexual exposure to an infected partner.[72,146,147] Among patients with anogenital gonorrhea, pharyngeal infection has been demonstrated in some studies in 3–7% of heterosexual men, 5–20% of women, and 10–25% of homosexual men. Among pregnant women, the proportion may be higher. Although exudative pharyngitis and sore throat may occur, pharyngeal gonorrhea is most commonly asymptomatic. Sore throat in some patients may be more related to a post-fellatio syndrome than to an infectious process. Asymptomatic pharyngeal infection resulting in DGI has been well described.

Diagnosis of pharyngeal gonorrhea should be made by culture because of the high prevalence of commensal *Neisseria* which cross-react with other diagnostic tests.

8.1.6. Disseminated Gonococcal Infection. Approximately 0.5% of patients with gonorrhea develop DGI. Patients with DGI have a local infection, rectal, urogenital, or pharyngeal, that is often asymptomatic. Host and organism factors are both important in permitting dissemination. As described earlier, organisms from patients with DGI are more likely to express LOS phase variants, rather than paraglobosyl or gangliosyl molecules, and to be serum resistant.[127,128,148,149] Organisms that cause DGI are generally more sensitive to antibiotics than those found in routine anogenital infections. DGI occurs more commonly in women than men; pregnant women are at even higher risk, probably because of suppressed immunity. Persons with terminal complement deficiencies also are at very high risk for dissemination and may experience multiple episodes.

DGI can be separated clinically into two syndromes. The first syndrome is a dermatitis-arthritis. Patients present with fevers, chills, polyarthralgias, or tenosynovitis. Joint and tendon symptoms are not migratory, but additive. Three to twenty petechial, papular, pustular, hemorrhagic, or necrotic skin lesions (frequently in combination) may be present on the distal extremities. Fingers, toes, hands, and wrists are commonly involved in an asymmetrical fashion. Blood cultures are positive for *N. gonorrhoeae* 50%. The second common syndrome is a septic arthritis, usually

monoarticular, affecting large joints. The knee is involved most commonly. Although the septic arthritis is secondary to a bacteremic process, blood cultures at this stage are rarely positive. Culture-negative cases are thought to result from either immune complex deposition or intra-articular killing of the organisms prior to arthrocentesis. DGI generally responds rapidly to appropriate antibiotic therapy. In a small proportion of patients with DGI, severe and potentially fatal complications such as meningitis or endocarditis[9] can occur.

8.1.7. Gonococcal Ophthalmia. Gonococcal ophthalmia occurs in neonates born to women with endocervical gonorrhea and adults who are exposed to infected secretions.[150,151] Adult gonococcal ophthalmia is occasionally seen in young adults with anogenital gonorrhea. Accidental autoinoculation is thought to be the cause of many cases. Purulent keratoconjunctivitis is seen clinically.

Neonatal gonococcal ophthalmia is rare in developed countries because of prenatal screening and universal prophylaxis.[152,153] In developing countries, however, gonococcal ophthalmia is still a major cause of blindness.[154] Clinically, diffuse redness and conjunctival swelling are seen first, followed by a profuse, purulent discharge from which the organism can be easily identified by Gram's stain and culture. Corneal scarring and blindness may occur if the infection is left untreated.

Neonatal gonococcal ophthalmia can be prevented by maternal screening and treatment, where indicated. In the United States, routine prophylaxis is given at birth with erythromycin, silver nitrate, or tetracycline. Tetracycline is currently preferred because of less irritation.

8.1.8. Pediatric Gonorrhea. Gonococcal infections in prepubertal children[152] should be considered evidence of sexual abuse unless proven otherwise.[107,155] Because of forensic implications, specific diagnosis is imperative. The chain of custody of cultures must be maintained, cultures from all sites should be confirmed by experienced laboratories, and positive specimens should be archived. In young girls either a symptomatic or an asymptomatic vulvovaginitis may be seen. Urethritis has been described in boys, and anorectal, rectal, and pharyngeal infection may be seen in both sexes.

8.2. Diagnosis

Infection with *N. gonorrhoea* should be included in the differential diagnosis of urethritis, cervicitis, septic arthritis, conjunctivitis, and sepsis in sexually active adults. Most pharyngeal infections with *N. gonorrhoeae* are asymptomatic. However, *N. gonorrhoeae* should be considered as a possible etiology of acute pharyngitis in patients with a history of orogenital sexual exposure. Newborns with conjunctivitis may be infected with *N. gonorrhoeae*.

A specific diagnosis of *N. gonorrhoeae* can usually be made by either Gram's stain or culture. The application of the Gram's stain and culture to specific gonococcal syndromes is detailed in Section 3.4.1. During the last decade, there have been major advances in nonculture diagnostic methods. Molecular diagnostic tests for *N. gonorrhoeae* are covered in Section 3.4.2.

9. Control and Prevention

9.1. Principles of Control

For control through public health intervention, we emphasize the importance of establishing priorities among gonorrhea cases for the implementation of measures such as intensive case-finding and epidemiological treatment. In other words, public health authorities must attempt to identify gonorrhea cases where intervention will have the highest yield in preventing further spread (see Sections 9.1.2 and 9.1.3). The mistaken assumption that every case of gonorrhea is equally important for the further spread of the disease must be dispelled. Failure to treat gonorrhea cases and to promote primary prevention among groups with a high rate of disease transmission significantly limits the chances of success. Different degrees of control are possible in different environments. Control programs in many developed countries are currently focused on efforts to decrease the prevalence of the disease. In other areas, attempts may be made to prevent only serious sequelae, i.e., gonococcal ophthalmia neonatorum and gonococcal PID.

9.1.1. Clinical Services. Provision of easily accessible clinical services and proficient laboratory support services are essential to control programs. Clearly, it is futile to engage in widespread screening and elaborate efforts to locate sexual partners, while waiting periods in clinics are long, patients with symptoms are being turned away, and the misdiagnosis and mismanagement of known cases are common. The establishment of practical clinical services should precede attempts at more sophisticated intervention and may in itself have a significant effect on the control of gonorrhea in some communities. To increase accessibility, all services related to the control of gonorrhea should be rendered free of charge, or at least not denied because of an inability to pay.

The prevention of gonococcal ophthalmia neonatorum is perhaps the only substantial intervention that is not rooted in STD clinical services. Even ophthalmia prophylaxis requires trained clinical personnel. Community education and promotion of primary prevention (e.g.,

abstinence, partner selection, and personal prophylaxis) should be based on epidemiological information derived from clinical facilities.

9.1.2. Epidemiological Process. Because of the large reservoir of asymptomatic and minimally symptomatic cases, especially in women, gonorrhea cannot be controlled solely by the application of diagnosis and treatment to cases with apparent symptoms. Public health intervention is targeted both at identifying potentially infected individuals and in preventing the further transmission of disease.

Direct disease control activities are usually a function of local health departments. Ideally, the epidemiological process should focus on five groups: new patients, sexual partners of patients, patients with repeated infections, health care providers, and community sources of health information. The basic information to be obtained from patients is directed toward identifying potentially infected partners and should include age, race, sex, place of residence, mobility, and special sociobehavioral features (e.g., prostitution, employment). Health care providers for the population at highest risk must be determined. Simple measures for doing so include (1) finding out from patients and their sexual partners where they are seeking health care; (2) making a survey of health care providers located near the places of residence of high-risk groups; and (3) seeking "hidden" health care providers (e.g., pharmacists, "street health providers", hotel physicians). In addition, a sample of physicians should be visited to find out the extent of their services to gonorrhea patients, if there is reason to suspect that a significant proportion of cases are not being reported. Health care providers serving high-risk groups must be assisted in the correct diagnosis and treatment of gonorrhea and encouraged to use appropriate intervention techniques.[156] For example, acute detention facilities (e.g., city jails) have been found to have extraordinarily high rates of disease.[157,158] Therefore, this may be a setting to increase diagnostic and treatment services.

Each community may have unique sources of health information. The quality and influence of these sources (peers, media, social groups, churches, opinion leaders) will vary for subgroups within the community. Liaison with these information sources should be sought by local health authorities.

9.1.3. Transmitters or Nontransmitters. Special emphasis must be placed on finding those who are infected. Patients who are most likely to be efficient transmitters of the disease deserve special emphasis in case-finding activities. Generally, efficient transmitters are those who are either asymptomatic or tend to ignore symptoms, who have a large number of different sexual partners, and who have limited access to medical care. A good indicator of a group with a high proportion of transmitters is the rate of repeated infection in the group. Efficient transmitters have also been linked epidemiologically to the core group (see Section 5.3).

9.1.4. Diagnostic Screening. Because of cost considerations, culture screening for case detection in gonorrhea control must be targeted to high-risk groups. The cost-effectiveness of screening will depend on the prevalence of the disease in the population and can be increased by concentrating on high-risk groups. However, although this measure will find cases at a lower cost per case, control effectiveness will depend on the proportion of existing cases missed by the screening procedure and other control strategies.

Populations screened should be carefully selected. For example, women presenting with signs or symptoms of other STDs, women distinguished by behavioral or demographic factors characteristic of high-risk groups (e.g., prostitutes), and women from groups in which the prevalence of the disease is high should be those selected for initial screening. The concept of repeated screening may be applied in a retrospective or prospective fashion. Retrospectively, women and men with a history of gonococcal infection should be screened whenever they visit a health facility. Prospectively, most authorities believe that immediate posttreatment evaluation (test of cure) is low yield. However, because of the high reexposure rate, it may be prudent to rescreen in 2–3 months. For example, careful studies of patients with gonorrhea have found that 10–15% will become reinfected within 3 months.[159]

Available resources will determine the number of screenings and the combinations of initial and repeat screenings that are possible within each locality. In most circumstances, only women are screened for gonorrhea. However, NAATs, which can be performed on urine, make noninvasive testing in men practical (see Section 3.4). In high-prevalence areas, screening in different clinical settings should also be considered (e.g., in antenatal, gynecological, or family planning clinics). Endocervical culture is the preferred screening method in women.

9.1.5. Epidemiological Treatment. Epidemiological treatment consists of providing full therapeutic doses of antibiotics to persons recently exposed to gonorrhea, while awaiting the results of laboratory tests to confirm a diagnosis. This practice is recommended because of the significant chance that the patient has been infected, the serious consequences of the disease, the relative safety and efficacy of treatment, the frequency with which people in high-risk groups default on appointments, and the risk of the spread of the disease in the community.

9.1.5.1. Counseling to Obtain the Simultaneous Treatment of Sexual Partners. Every gonorrhea patient should

receive counseling with the aim of ensuring that (1) the patient will return for reexamination; (2) the patient will advise his or her sexual partners to seek examination and treatment; (3) the patient will abstain from sexual contact until the sexual partners have been examined and treated; and (4) should the patient be reinfected in the future, he or she will bring recent sexual partners along to the health care facility.

9.1.5.2. More Intensive Case Management. These techniques range from brief motivational educational sessions with individual patients to systems using referral cards and to actual personal interviews with patients that will enable public health workers to visit the patient's sexual partners in the community and offer treatment. Individual personal interviews to learn the names and whereabouts of sexual contacts and, in particular, community visits by health workers to locate these contacts may be possible in some areas. Whatever methods for providing epidemiological treatment to patient's sexual partners are used, they may not need to be used uniformly for all patients.

9.1.5.3. Priorities for Epidemiological Services. The aim of contact tracing is to provide epidemiological treatment for those most likely to have transmitted the disease recently and most likely to continue transmitting it in the future. Contact tracing also requires the accessibility of the index case to the counselor or public health worker. Granting this, priority for epidemiological services should be given to these groups of patients, symptomatic men and members of high-risk groups (Table 2). When the sexual partners of these groups of patients are examined, the rate of asymptomatic infection is high. If the control organization is still weak, initially it may be most practical for epidemiological services to concentrate on men with symptomatic gonococcal urethritis.

9.1.6. Health Education. Health education has been widely accepted as an important tool in the control of STDs because of increased recognition of the behavioral and sociocultural factors involved in their prevention, transmission, diagnosis, and treatment. Medical and organizational measures by themselves have proven to be unsatisfactory. In some countries, sex and health education is neglected, particularly among the young. The consequent ignorance about STDs may hinder their control because infected patients may be slow to take advice. Decisions and action to adopt control and preventive measures in relation to STDs depend on several factors, such as information and misconceptions about these diseases, changes in beliefs about them and in attitudes toward them, prevailing cultural views and social norms, and the way patients are received by the STD health providers.

Health education activities may be aimed at making the public aware of the STD problem in the community, at seeking the active cooperation of groups and individuals in control activities, at informing groups at risk about control and preventive measures and motivating them to adopt these measures, at educating young people to consider the health-related aspects of their sexuality, at preparing personnel for their educational functions in the control program, and at orienting services at the relevant clinics toward the needs of their clients.

9.1.7. Partner Management. One of the most important interventions in STDs has been partner management. This has been particularly challenging, especially in environments where partners are not accessible. This can be particularly difficult in areas where commercial sex workers or gay men with anonymous sex partners are operative. Another challenge, especially in the management of gonorrhea and chlamydia infections, has been in accessing partners, especially in areas where there have been poor resource availability. For example, a variety of studies have demonstrated that interventions are much more effective than traditional self-referred partner management strategies; however, resources are difficult to access. The traditional approach has been health department outreach, where trained disease intervention specialists bring individuals identified as sexual contacts of infected patients into the clinic for evaluation and treatment, or alternatively, assure referral. An alternative approach has been providing *partner-delivered therapy.* Under this approach, an individual partner receives therapy which he/she would then give to his/her partner at home .[160,161] This approach has been utilized in a number of cities, but faces regulatory challenges. The regulatory challenges include liability issues (for example, the practitioner is providing therapy for an individual who is technically not the practitioner's patient), reimbursement issues, especially when both partners are not part of the same health plan, and regulatory issues from pharmacy and medical boards. This approach also requires a level of trust between sexual partners. Nevertheless, these barriers have been overcome in a variety of states. The most

Table 2. Examples of Priority Criteria for Disease Intervention[a]

Prostitutes
Women with pelvic inflammatory disease
Symptomatic men
Cases of treatment failure (possibility of resistance)
Residence within a defined "core" area
Antimicrobial-resistant infection
Use of "crack" cocaine
Large number of sexual contacts

[a]These are examples of criteria used by different communities. Not all may be applicable to any one community.

important study in addressing partner management issues was conducted by Golden. He demonstrated that provision of partner therapy either through patient-delivered therapy or provision of partner therapy through a network of referral pharmacies substantially reduced gonorrhea reinfection in the index patients. These data, although fairly conclusive, however, represent an enormous investment of resources, which may not be applicable to most areas.

9.2. Macro-Level Epidemiological Approaches

Designing control strategies also requires assessing the impact or sociogeographic effects. STDs predominantly affect specific demographic subgroups. Within the broad population strata, STDs are often concentrated in areas where poverty and other limitations on health care access exist. This has resulted in development of the "core group" concept.[24,162–164] The core groups are population subgroups which are disproportionately impacted by STDs and which often act as the endemic reservoir of disease within a community. These may be either sociologically or geographically defined. For example, in developing countries, the predominant core groups are long-distance truck drivers and commercial sex workers, whereas in the United States, there is often a direct link to drug use. On a community level, gonorrhea is often associated with other indicators of social disruption, such as a high number of liquor stores and abandoned buildings.[165,166]

In the United States and Western Europe, core groups are often defined geographically as residents of defined core areas which typically are socioeconomically depressed. In the US urban environment, core areas have been well documented for gonorrhea and other STDs such as syphilis and HIV. Within a core area, disease incidence may be 20–30 times that of surrounding areas. For example, in Baltimore we have identified discrete core areas where the reported gonorrhea rate in 1994 for persons aged 15–39 years was 6,821/100,000 for men and 4,341/100,000 for women and areas where primary and secondary syphilis incidence had similar disproportionately high rates.[25,167]

The transmission efficiency of gonorrhea and syphilis through unprotected sexual exposure has been empirically estimated to be 50–70% per exposure and treatment effectively breaks the transmission chain. Therefore, under most circumstances, introduction of gonorrhea into a community free of infection should not result in a sustained epidemic. Community-based models of STD transmission therefore postulate that core areas or epidemiologically defined core groups are critical to maintaining high rates of gonorrhea. In these models, cores are characterized by a high transmission density, an empirical function that is dependent on characteristics of the sexual network. In contrast to many other infectious diseases, STD transmission is dependent on behavior, i.e., sexual intercourse. STD transmission is therefore limited to sexual networks, i.e., the interrelated sexual connections of a defined social group.

9.2.1. Social Networks. Traditional STD intervention approaches have used partner notification as a major tool in control programs. As discussed earlier, for diseases like gonorrhea—where the incubation period is short—or diseases with prolonged latency periods (asymptomatic infection) that is efficiently transmitted—such as chlamydia—partner notification may not work. In contrast, syphilis has been traditionally controlled with partner notification using the rationale of the "critical period". As a control tool, however, partner notification has never been fully and formally evaluated. In settings where partners are not named—such as in drug-related prostitution—the process fails. New approaches have utilized understanding the social network,[168,169] i.e., those individuals who are associated with the infected individual. These approaches appear to be successful in identifying additional infected persons.

9.3. Personal Prophylaxis

Condoms, when used appropriately, are highly effective in preventing transmission of gonorrhea and other STDs.[170–173] Latex condoms are recommended, since natural membrane condoms contain pores that may allow the transmission of small viral particles, such as HIV. These pores are not present in latex condoms. Although there is substantial current work on microbicides, those tested to date have not been shown to be effective in preventing incident gonococcal infection.[174]

9.4. Possibilities of Immunization

The LOS, OMP, and pili of *N. gonorrhoeae* have been viewed as potential candidates for vaccine development.[109,116,134] Vaccine development has been complicated by the lack of an animal model, antigenic diversity among strains, and antigenic variation within strains over time.

The failure of OMP and pilus vaccines has focused attention on LOS, particularly paraglobosyl LOS. Seroepidemiological surveys and resistance to experimental infection provide compelling support for the development of a paraglobosyl LOS vaccine, but formulating such a vaccine will be a daunting undertaking, given the endotoxic

properties of LOS and the molecular mimicry of human paraglobosyl glycosphingolipids by paraglobosyl LOS. It is unlikely that a simple, effective vaccine can be developed in the near term, although technical advances may lead to success in the future.

10. Unresolved Problems

The gonococcus has historically demonstrated great versatility and adaptability. In the next few years, it would not be unreasonable to expect the continued development of antimicrobial resistance. Quinolone resistance appears to be particularly ominous.

However, we may also expect to see a continued decrease in gonorrhea incidence because of improved diagnosis, which in turn will enhance control. The new NAATs are a major advance that facilitate noninvasive screening. From a practical standpoint, gonococcal NAATs often are combined with *Chlamydia* NAATs. However, NAATs are more expensive than traditional tests and require advanced laboratory resources and investment.

Finally, advances in glycobiology and immunology may finally point the way toward effective local preventive measures for gonorrhea and other STDs and make possible the development of a safe and effective gonococcal vaccine.

CHAPTER 17

Haemophilus influenzae

Janet R. Gilsdorf

1. Introduction

Haemophilus influenzae, a common commensal of the pharynx of humans, is considered part of the normal pharyngeal flora. In addition, it is an important cause of human infections. Strains that possess one of the six polysaccharide capsules, types a through f, cause invasive infections such as bacteremia, meningitis, septic arthritis, epiglottitis, and facial cellulitis, with type b infections being significantly more common (greater than 90%) than types a and c–f. Use of the highly successful type b vaccine, composed of the type b polysaccharide conjugated to one of several protein carriers, has resulted in dramatic reductions in rates of invasive infections in the United States and in many Western countries. Strains with no capsule, the so-called non-typeable strains, are frequent causes of localized infections such as otitis media and sinusitis in children and adults, as well as bronchitis and pneumonia in adults. While the organism lives asymptomatically in the pharynges, it does not cause localized pharyngitis. No vaccine is yet available to protect against infection with non-typeable strains.

2. Historical Background

H. influenzae are gram-negative, pleomorphic bacilli originally described by Pfeiffer in 1892.[1] Known as the Pfeiffer bacillus, it was isolated from patients with influenza and assumed to be the causative agent of what is now known to be viral influenza.[2] Ultimately its association with influenza was recognized to be secondary rather than causal. Subsequently it was named *Haemophilus influenzae,* referring to its absolute heme requirement for growth (heme = blood, philus = loving) and its historically presumed role in influenza. In 1931, Margaret Pittman classified *H. influenzae* by the presence of one of six antigenically distinct polysaccharide capsules (types a–f), based on the ability of the bacteria to be agglutinated by capsule-specific typing antisera.[3] Strains that lack capsule (non-typeable) are not agglutinated by any of the typing antisera.

In the past century, *H. influenzae* has been at the center of a number of important scientific discoveries. Fothergill and Wright, in 1933, recognized the association of protection against *H. influenzae* meningitis with the level of bactericidal activity of blood, thus describing the role of age-related immunity in protection against infection with encapsulated bacteria.[4] In 1980, Smith and colleagues described the mechanism with which DNA is taken up by *H. influenzae*.[5] This observation explained at the molecular level the process of transformation of DNA by competent bacterial cells. In the early 1980s, Porter Anderson[6] as well as John Robbins and Rachel Schneerson[7] pioneered the techniques of conjugating protein carrier molecules to the *H. influenzae* capsular polysaccharide polyribosyl ribitol phosphate (PRP). This technology is now used in the preparation of conjugated polysaccharide vaccines that prevent *H. influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis* infections. Finally, in 1995, *H. influenzae* strain Rd was the first free-living organism to undergo DNA sequence analysis of its entire genome,[8] ushering in the era of complete genome analyses of bacteria with the resultant increased understanding of bacterial pathogenesis, physiology, and genetic variability.

3. Methodology

3.1. Epidemiologic Reporting

Surveillance of invasive *H. influenzae* infections in the United States has been conducted by the National Notifiable Diseases Surveillance System (NNDSS, http://www.cdc.gov/EPO/DPHSI/nndsshis.htm) which is operated by Centers for Disease Control and Prevention (CDC) in collaboration with the Council of State and Territorial Epidemiologists (CSTE) and published weekly in MMWR. Data include weekly and annual national cumulative statistics on type b, non-type b, and unknown serotype infections in children <5 years old (Table I) as well as weekly and annual regional and state by state data for invasive *H. influenzae* infections of all serotypes in all ages (Table II, Part 2) and are available on the CDC Web site from 1996 to the present (http://www.cdc.gov/EPO/DPHSI/annsum/index.htm).

In addition, surveillance of *H. influenzae* invasive infections is conducted by the Active Bacterial Core (ABC) surveillance system, a component of the CDC's Emerging Infections Program Network (EIP), a collaboration between CDC, state health departments, and universities, consisting of 10 sites across the United States, representing a population of over 38 million persons (http://www.cdc.gov/ncidod/dbmd/abcs/survreports.htm). Data collected include invasive infections caused by type b, non-b, non-typeable, and unknown types stratified by age groups. Cases of meningitis and bacteremia without focus, with their respective mortality rates, are reported.

Non-invasive *H. influenzae* infections are not reportable in the United States.

3.2. *H. influenzae* Typing Methods

Epidemiologic studies of *H. influenzae* infections require a system of clustering the causative organisms in a meaningful way. A number of typing systems have been used to group strains as alike or different based on phenotypic characteristics such as capsular type, biotype, outer membrane protein type, or multilocus enzyme electrophoresis (MLEE) type. More recently, a number of molecular typing systems have been used to cluster *H. influenzae* strains based on restriction fragment length polymorphisms (RFLP), polymerase chain reaction (PCR) fragment sizes, and DNA sequences of various regions of the *H. influenzae* genome.

3.2.1. Phenotype-Based Typing Methods

3.2.1.1. Capsule and Capsular Typing. Classical serotyping requires specific reagents and skilled, experienced laboratory technologists and interlaboratory variability in typing results is unacceptably high using this technique.[9] Thus, newer molecular amplification methods have been developed[10] that utilize PCR amplification of the capsular gene regions. One set of primers is used to amplify the *bexA* region, which is required for export of the capsule to the cell surface and is conserved in all encapsulated *H. influenzae* strains. Recent data demonstrating allelic variation in *bexA* among types a, e, and f strains suggest that detection of this gene will be improved with an additional primer set.[11,12] A second series of primers, which amplify the type-specific domain of the *cap* gene region of typeable strains, are used to determine the specific capsular type, a–f. Allelic variants of *pgi*, which encodes phosphoglucose isomerase, cluster with specific *H. influenzae* serotypes, suggesting *pgi* genotyping may serve as a marker for serotype.[13]

3.2.1.2. Biotyping. *H. influenzae* have been classified by biotype on the basis of three biochemical activities—the production of indole and the presence of urease and ornithine decarboxylase activities.[14] Eight biotypes have been identified, see Table 1; most clinical isolates are biotypes I, II, or III. While specific biotypes have been associated with virulent strains,[15] this technique is not discriminatory enough to be useful in clustering *H. influenzae* for meaningful epidemiologic investigations.

3.2.1.3. Outer Membrane Typing. Early attempts at sub-typing *H. influenzae* used outer membrane protein profiles, generated by digesting the bacterial outer membranes with detergents or by sonication and separating the outer membrane fragments by gel electrophoresis.[16,17] This technique was used to track transmission of *H. influenzae* strains[16] and to compare commensal strains with otitis media strains from the same subject.[18] Outer membrane typing has been replaced by newer molecular-based methods for identifying related *H. influenzae*.

3.2.1.4. Multilocus Enzyme Electrophoresis (MLEE). MLEE differentiates *H. influenzae* strains based on the electrophoretic pattern differences of 15–17 metabolic enzymes.[19–21] In the largest study of *H. influenzae* electrophoretic types among encapsulated strains (mostly type b)

Table 1. Biotype Characteristics of *Haemophilus influenzae*

H. influenzae biotype	Indole production	Urease activity	Ornithine decarboxylase activity
I	+	+	+
II	+	+	–
III	–	+	–
IV	–	+	+
V	+	–	+
VI	–	–	+
VII	+	–	–
VIII	–	–	–

280 types were identified.[19] Type b strains were found to fall into two major phylogenetic groups, division I (in which strains exhibit duplication of the *cap* gene region, which is flanked by IS*1016* elements) and the much smaller division II (in which strains have a single copy of the *cap* gene region, are not flanked by IS*1016* elements, and the *cap* region may be located in a different chromosomal site from Division I strains[22]). Further MLEE analysis showed that non-typeable strains are phylogenetically distinct from type b strains and more heterogeneous.[23] MLEE is costly and time intense to perform and has largely been abandoned.

3.2.2. Molecular-Based Genotyping Methods. The classical typing systems to characterize groups of *H. influenzae*, capsular typing and biotyping, are limited by their ability to identify only seven serotype groups (including non-typeable) and eight biotype groups. Recently, molecular typing systems have been developed to expand the ability to group *H. influenzae*. Each molecular typing system relies on various genetic alterations that give rise to polymorphisms in the *H. influenzae* genome and distinguishes strains by characterizing different molecular parameters of the strains (Table 2). Thus, strains grouped as similar by one technique may not group as similar by another.

For restriction fragment-linked polymorphism (RFLP)-based methods, such as pulsed field gel electrophoresis (PFGE), genomic DNA is digested with rare-cutting restriction enzymes and the resulting DNA fragments are separated by gel electrophoresis and the patterns analyzed. In a related RFLP-hybridization method (such as ribotyping) genomic DNA is digested with frequent-cutting restriction enzymes and separated; resultant DNA fragments are then interrogated with gene-specific nucleic acid probes. For polymerase chain reaction (PCR)-based typing methods (such as the random primer methods RAPD and ERIC as well as repetitive element PCR [rep-PCR] techniques), specifically designed primers hybridize to the complementary genomic DNA and the intervening DNA sequences are amplified; the resultant DNA amplicons are then separated by gel electrophoresis and the patterns analyzed. For DNA sequence-based methods (such as 16S rRNA typing, multilocus sequence typing (MLST), and multilocus variable number tandem repeat analysis (MLVA)), primers are designed to amplify the region of interest, the intervening DNA sequences are amplified, the amplicons are subjected to DNA sequence analysis, and the sequences are compared.

The ideal typing system is capable of distinguishing apparently unrelated strains from each other but is not so discriminatory that each isolate is designated a unique type. Any system must be validated using epidemiologically related and unrelated strains and must test strains passed in the laboratory several times to assess the stability of the typing parameters. The results of typing by molecular-based methods may differ dramatically in the number of unique patterns observed among various *H. influenzae* strains, reflecting increased clonality among type b strains compared to non-typeable strains, and in the definition of unique genotypes.

When molecular-based typing methods that utilize electrophoretic banding differences are used to analyze large numbers of strains, the resulting patterns are often analyzed by computer-based cluster analysis methods in which a Dice coefficient matrix of pairwise differences in the pattern profiles is constructed and the pattern divergences calculated from this matrix are displayed in a dendrogram constructed by the unweighted pair-group method using arithmetic averages (UPGMA).[24] While these distance (phenetics) methods accurately display clustered strains, they are not excellent methods of displaying phylogenetic data to make

Table 2. Molecular-Based Typing Methods of *Haemophilus influenzae*

Methods	Discriminator	Type based on
RFLP		
PFGE	Sizes of restriction fragments	Patterns of bands on a gel
PFGE + hybridization	Sizes of restriction fragments that hybridized to gene-specific probes	Patterns of bands on a gel
PCR		
RAPD™, ERIC™, RepPCR	Sizes of PCR-generated amplicons	Patterns of bands on a gel
DNA sequence		
MLST, MLVA, 16sDNA	Nucleotide sequences of PCR-generated amplicons	Nucleotide sequence differences

PCR = polymerase chain reaction
RepPCR = repetitive sequence PCR
MLST = multilocus sequence typing
MLVA = multilocus variable number tandem repeat analysis

inferences on evolutionary descent,[25] which are better displayed using character (cladistic) methods.[26,27]

3.2.2.1. Restriction Fragment Length Polymorphism (RFLP)-Based Typing Methods. Ribotyping: Ribotyping distinguishes bacterial strains by restriction length polymorphisms of their genetic regions that contain genes encoding ribosomal RNA. The bacterial DNA is digested with frequent-cutting restriction endonucleases, the resulting bands are separated by gel electrophoresis, and the gels are interrogated with a labeled rRNA probe.[28] DNA from 120 *H. influenzae* strains (77 were type b, the remainder were non-typeable) digested with *Hae* III and *Eco* RI yielded three and six, respectively, different ribotype groups.[29] In another study, DNA from 75 non-typeable strains digested with *Eco* RI yielded 45 ribotype groups.[30] In a study from Taiwan, ribotyping yielded 6 patterns among 55 type b strains, 9 patterns among 10 isolates of non-b-typeable strains, and 12 profiles among 22 non-typeable *H. influenzae*,[31] thus confirming increased diversity among non-typeable strains compared to type b strains. Ribotyping, while potentially useful in genotyping *H. influenzae*, was less discriminatory than pulsed field gel electrophoresis.[30]

Pulsed field gel electrophoresis (PFGE) typing: PFGE, often considered the gold standard of molecular genotyping, distinguishes bacterial strains by difference in the sizes of their restriction fragments. The strain DNA is digested with rare-cutting (8 base pair) restriction endonucleases (often *Sma* I, *Spe* I, or *Eag* I are used with *H. influenzae*) and the resulting bands are separated by gel electrophoresis. The differences in banding patterns result from strain-to-strain differences in the presence and location of the restriction endonuclease sites across the *H. influenzae* genome. Characteristically 5–20 fragments are generated, ranging in size from 10 to 800 kb in length. See Figure 1.

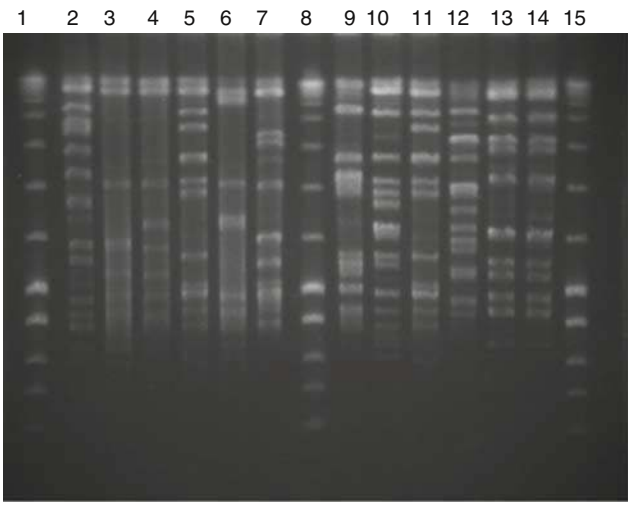

Figure 1. Patterns of bands on a gel: PFGE of DNA of *Haemophilus influenzae* isolated from children in a day care center and digested with the restriction enzyme *Sma* I. Lanes 1, 8, and 15 = fragment size markers. Strains in lanes 5 and 11 and in lanes13 and 14 are genotypically identical.

RFLP typing strategies were originally designed to identify related organisms during outbreak of infectious diseases, and standard guidelines for interpreting the DNA restriction patterns generated by this technique for outbreak investigation have been developed.[32] Computer simulation digestion of bacterial DNA by restriction enzymes demonstrated that errors associated with both band determination and band matching contributed to variable PFGE results. Use of multiple enzymes improved the fidelity between the PFGE results and the true sequence similarities.[25,33]

PFGE has been used to document relationships between *H. influenzae* strains isolated from children attending the same day care,[34,35] between strains serially isolated from the same individual,[36] between strains from household contacts of patients with invasive *H. influenzae* infections,[37,38] and between non-β-lactamase-resistant *H. influenzae*.[39,40] PFGE has shown the limited diversity of type a strains isolated during outbreaks in Alaska and on the American Indian reservations[41,42] and the absence of change in population structure of strains isolated before and after introduction of the Hib vaccine.[43,44] Repeatedly, except in outbreak situations, PFGE has shown the highly diverse phylogenetic structure of *H. influenzae*, particularly that of non-typeable strains.

3.2.2.2. Polymerase Chain Reaction (PCR) Fragments-Based Typing Methods. PCR-based methods rely on analysis of DNA fragments derived from amplification of specific bacterial genome regions, using primers that hybridize with predetermined nucleotides that are present, usually, within or flanking the genomic region of interest.

Random amplified sequences-based genome typing methods: Random amplified sequences typing (RAPD™) is a PCR-based technique in which amplicons are generated using nucleic acid primers with no specificity for *H. influenzae* DNA. RAPD using either AP1 or AP2 primer sets was more discriminatory in *H. influenzae* than ribotyping, yielding 10–13 (respectively) bands for analysis.[29] In many studies, RAPD results have been found to be labile with poor reproducibility on repeated testing of the same sample,[37,45,46] although commercial kits may reduce the poor reproducibility to some extent.[47]

Enterobacterial repetitive intergenic consensus (ERIC) typing is a PCR-based technique in which amplicons are generated using nucleic acid region primers that hybridize with many gene regions in *Escherichia coli.* These specific gene regions have been shown to be absent in *H. influenzae* so when used to type *H. influenzae*, this technique actually

depends on amplification of random sequences. ERIC, using ERIC I primers, was found to be more discriminating than ribotyping for *H. influenzae*.[30] The poor reproducibility of random amplified sequence typing may be related to the low stringency required of the amplification reaction to allow hybridization of the random primers.[30]

Repetitive element PCR typing: Repetitive element typing utilizes PCR to amplify DNA regions located between repeated sequences in bacterial genomes. The sequence of *H. influenzae* strain Rd revealed a number of repeated sequences and several of these have been used for genotyping.

Bruant et al. amplified fragments using primers containing the 23-base pair sequence commonly called intergenic dyad sequence (IDS), which is found in multiple copies throughout the *H. influenzae* genome, commonly in pairs as inverted repeats.[48] The results showed approximately 10 bands that could be used for analysis and 62 different patterns were identified among 66 non-typeable strains; epidemiologically linked strains showed identical or closely related patterns. Reproducibility using the IDS typing technique was excellent, possibility because of the high stringency conditions possible with use of the *H. influenzae*- specific primers.

The genome of *H. influenzae* strain Rd contains 1465 copies of the 9 base pair uptake signal sequence (USS) 5'-AAGTGCGGT-3'.[8] Experience with the use of these repeats in repetitive element typing has shown the generation of overly complex banding patterns because of the large number of USS repeats.[48] USS typing using different stringency conditions may have a role as an initial screen in a multi-stage typing system.[36]

3.2.2.3. Sequence-Based Genome Typing Methods. Standard gel electrophoresis-based techniques to type *H. influenzae* show considerable lab to lab variability and are subject to variations in laboratory conditions used to perform the assays. DNA sequence-based techniques, on the other hand, yield unambiguous data that may readily be shared from lab to lab.

16S rRNA typing: Sequence differences of 16S ribosomal RNA genes have formed the basis for genotyping several pathogenic bacteria, including *H. influenzae*.[49] The level of discrimination between strains was similar to multilocus sequence typing (see below), although the two methods grouped the non-typeable strains differently. *H. influenzae* possess six 16SrRNA operons that may not be identical in sequence,[8] potentially complicating sequence analysis of strains possessing differing 16S rRNA genes.[50]

Multilocus sequence typing (MLST): MLST was developed as an epidemiologic tool and has been widely used to genotype a large number of bacterial species.[51] The principle of the method relies on indexing variation in the slowly evolving core genes.[52] To genotype *H. influenzae* the MLST technique uses the sequences of seven genes that encode central metabolic enzymes ("housekeeping genes"), *adk*, *atpG*, *frdB*, *fucK*, *mdh*, *pgi*, and *recA*. Sequences of approximately 440 bp of each gene are concatenated for analysis. Each unique allele of each gene is assigned an arbitrary identifier, and the sequence types (ST) of the strains are defined on the basis of their allelic profile over the seven loci examined. An open source repository for *H. influenzae* sequences has been established, hosted at Imperial College in London and developed through funding by the Wellcome Trust (http://haemophilus.mlst.net). Over 600 strains are included in the *H. influenzae* database but are not an unbiased representation of the whole population of *H. influenzae* as strains isolated from clinical specimens are overrepresented.

The two approaches for examining the levels of relatedness between strains using MLST data include (1) clustering procedures based on pairwise differences in allelic profiles, either on a gene-by-gene basis or by concatenating the data for all seven loci, and (2) phylogenetic analysis based on allele sequences. Because the UPGMA clustering algorithm, based on allelic mismatches, may not adequately represent the pattern of events that occurred during genetic diversification, eBURST, which identifies the most parsimonious founding genotypes, has been developed to incorporate a more realistic model of clonal expansion,[53] see Figure 2.

MLST has been used to characterize the phylogenetic relationships of encapsulated and non-encapsulated *H. influenzae*.[54] Recombination was identified among the seven housekeeping genes studied (particularly evident in *pgi*, *recA*, *mdh*, and *frdB*) and appeared to be less frequent among encapsulated strains. The average number of alleles for each of the gene loci was 27, with a range of 22–36. Among 26 non-typeable isolates, 19 sequence types were identified, and with one exception, isolates with identical sequence types were epidemiologically close linked. A recent modification of MLST uses a multiplex format to amplify all seven genes in the same PCR reaction.[55]

Multilocus variable number tandem repeat analysis (MLVA): Tandem repeat regions possessing variable numbers of repeats have been identified in almost all bacterial species. The number of repeats in each repeat locus varies from strain to strain because of genetic instability of the repeat regions[56] and forms the basis for MLVA genotyping. In *H. influenzae*, short 2–7 base pair tandem repeats are extremely common in the genome and are often associated with virulence genes, where the number of repeats correlates with expression or non-expression of the virulence factor, through a mechanism termed phase variation (see Section 4.3.2.4, Phase variation). In MLVA typing, primer pairs amplify DNA regions that contain the repeat sequences,[57] the amplicons are then sequenced, and the number of repeats

will be

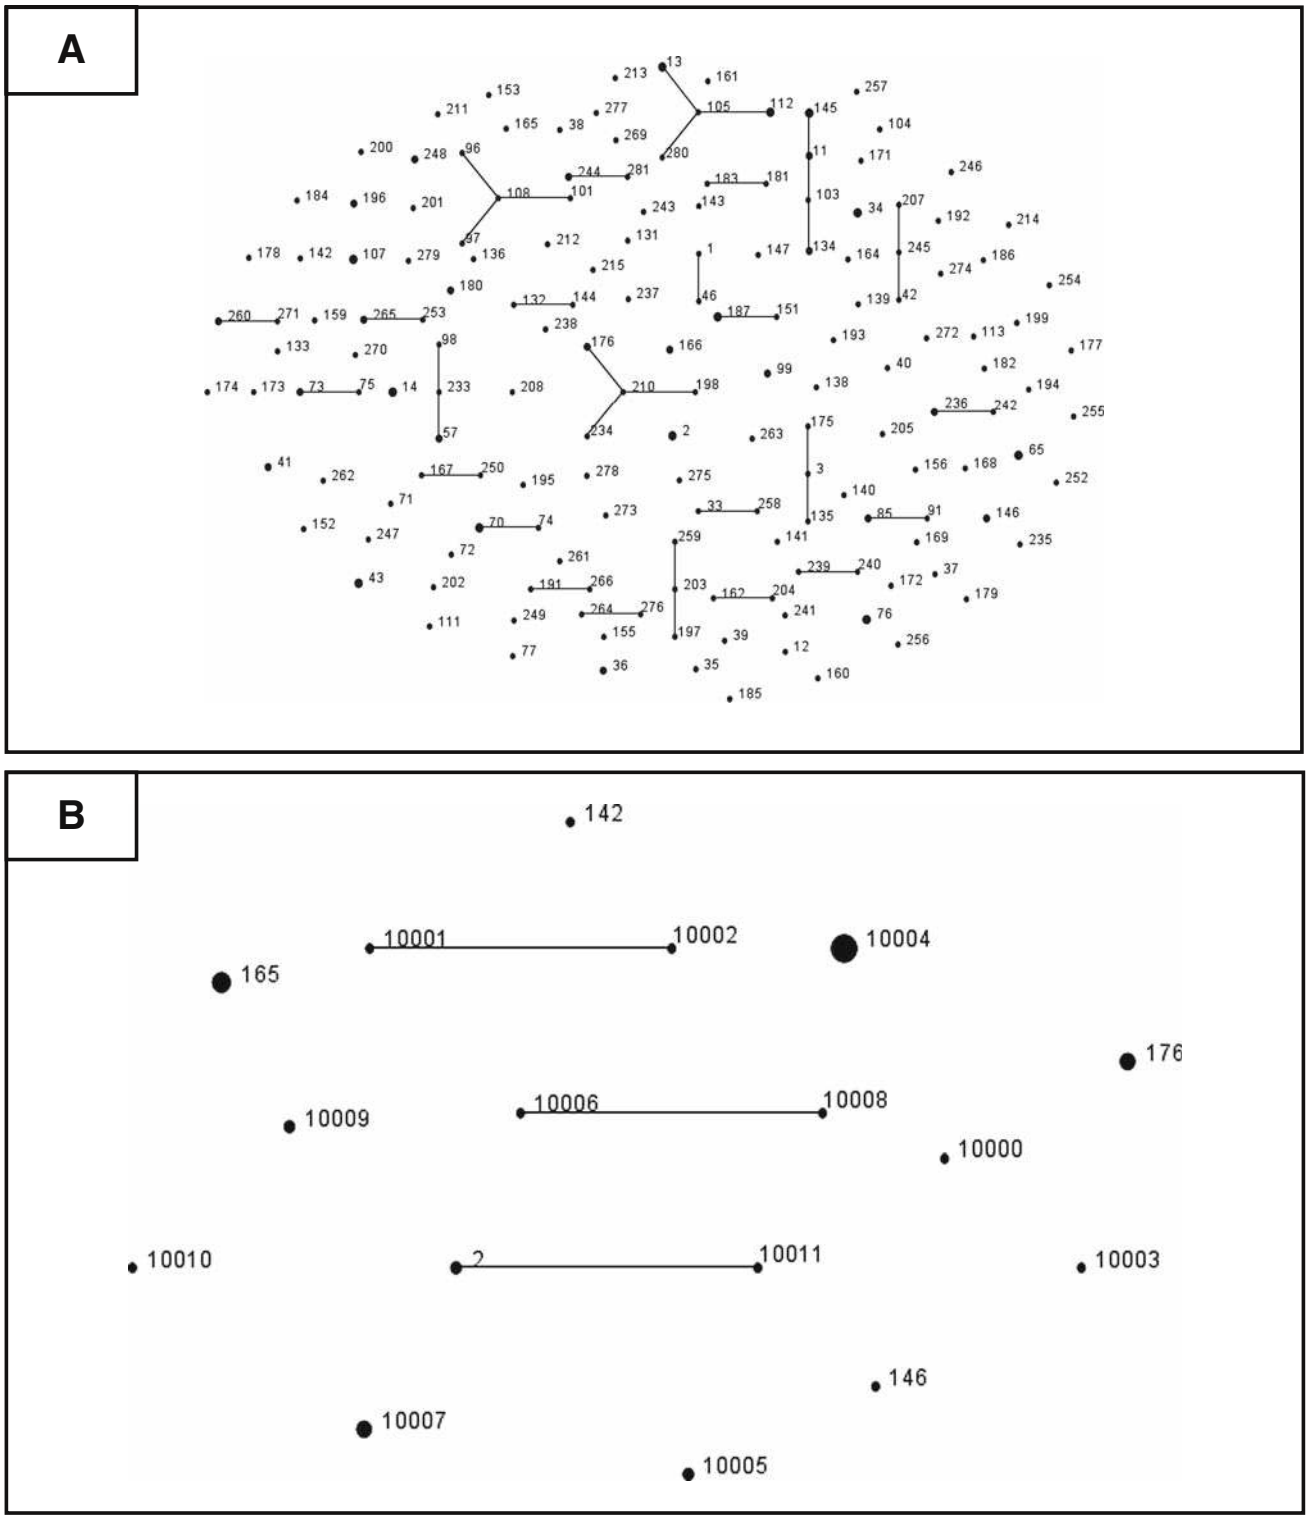

Figure 2. Multilocus sequence patterns of non-typeable *H. influenzae*, **A**, and of type b *H. influenzae*, **B**.

found in the sequence are used to establish the genotype. Further refinement of this technique has used four primer sets, to amplify areas with three or four repeats composed of sequences of 5–12 base pairs.[55] MLVA typing was found to be more discriminating for differences in type b *H. influenzae* than was MLST.[55]

3.3. Laboratory Diagnosis of *H. influenzae* Infection

The diagnosis of an infection caused by *H. influenzae* relies, first, on a clinical suspicion that these bacteria may be the causative agent of a patient's symptoms. There is no role for screening tests to facilitate early detection of *H. influenzae* infections. Positive throat or nasal cultures for *H. influenzae* do not predict an association with a specific clinical infection, as many individuals are colonized with *H. influenzae* and only a few of those colonized experience disease.

3.3.1. Culture. The most reliable diagnostic test for *H. influenzae* disease is bacterial culture of material obtained from the site of infection. These organisms are fastidious and require enriched nutrient media containing factor X (heme) and V (nicotinamide adenine dinucleotide, or NAD) for growth. The ideal laboratory growth conditions are 35°C with 5–10% CO_2. Clinical microbiology laboratories use chocolate agar to identify *H. influenzae* from specimens other than blood and automated culture systems to process blood specimens.

Most invasive *H. influenzae* infections are associated with concomitant bacteremia and blood culture may be critical to identifying the causative organism. In children, the level of *H. influenzae* bacteremia correlates with the severity of the infections, i.e., patients with $\geq$100 colony-forming units per milliliter were more likely to have meningitis.[58] Most patients with invasive type b infections have $>$15 colony-forming units per milliliter. Thus, the organisms can often be detected in samples containing relatively low blood volumes, and successful recovery of *H. influenzae* usually requires only a single, aerobic blood culture.[59] Prior receipt of an antibiotic to which *H. influenzae* are sensitive may compromise the ability to detect these bacteria by culture.

In addition to blood cultures, cultures of material obtained directly from the site of infection is important in establishing the causative organism, such an cerebrospinal fluid from patients with meningitis, joint fluid from patients with septic arthritis, and pleural fluid from children with pneumonia with pleural effusion. Blood cultures from children or adults with non-typeable *H. influenzae* respiratory tract infections such as pneumonia, bronchitis, sinusitis, or otitis media rarely reveal the causative bacteria. While no longer routine clinical practice for patients with uncomplicated acute otitis media, cultures of the middle ear fluid is the only way to diagnose *H. influenzae* acute otitis media. *H. influenzae* may also be isolated from sinus aspirates and bronchial-alveolar lavage specimens.

3.3.2. Identification of *H. influenzae*. In clinical microbiology laboratories, *H. influenzae* are characterized as gram-negative, pleomorphic bacilli that grow on chocolate agar but not sheep's blood agar and require X and V factors for growth. Factor V (NAD) requirement is assessed by bacterial growth surrounding NAD-containing discs placed on a bacterial lawn inoculated on nutrient agar plates or by satellitism around *Staphylococcus aureus* strains that secrete NAD (factor V).[60] Heme (factor X) requirement is assessed by bacterial growth surrounding heme containing discs or by failure of the colonies to elaborate porphyrin, indicating that they do not synthesize heme and, thus, require factor X.[61] *H. influenzae* are classically distinguished from the closely related, but not pathogenic, *Haemophilus haemolyticus* by failure to lyse horse or rabbit erythrocytes.

Recent studies have shown that *H. haemolyticus* often spontaneously lose hemolytic activity and, thus, appear identical to *H. influenzae* by standard classification methods. *H. influenzae* may be distinguished, however, from non-hemolytic *H. haemolyticus* by the presence of *iga*, which encodes IgA protease[60]; presence of a specific epitope in the outer membrane protein P6[62]; presence of *sodC* or its cognate protein copper–zinc superoxide dismutase[63]; and a unique amplification product following polymerase chain reaction using *H. influenzae*-specific 16S rDNA primers.[62] Although *H. haemolyticus* strains are not associated with disease, between 10 and 40% of *H. influenzae*-like isolates from the respiratory tracts of patients with chronic obstructive pulmonary disease (COPD) or of asymptomatic individuals[62,64] are non-hemolytic *H. haemolyticus*.

3.3.3. Antigen Detection. Commercial kits are available to detect the capsular polysaccharide, PRP, of type b *H. influenzae* in serum, cerebral spinal fluid, and urine and may be used to confirm type b *H. influenzae* infection.[65] Because accurate test interpretation is highly dependent on the experience of the technician, this test is not widely used in clinical microbiology laboratories.

3.3.4. Polymerase Chain Reaction (PCR). While PCR has been used to detect *H. influenzae* DNA in sterile middle ear effusions[66] and from the blood of patients with meningitis or pneumonia,[67] such nucleic acid amplification techniques are not routinely used for the diagnosis of *H. influenzae* infections.

3.3.5. Serology. Infection with type b *H. influenzae* results in stimulation of type b capsule antibodies in children over age 2 years. The development of an immune response to the capsule or to non-type b antigens, however, requires 1–2 weeks and is not clinically useful in diagnosing an acute infection with *H. influenzae* type b.

4. Biological Characteristics of *H. influenzae*

The *Haemophilus* genus resides in the Gammaproteobacteria and is a member of the family Pasteurellaceae, which also includes the genera *Actinobacillus* and *Pasteurella*.

4.1. Growth Requirements

H. influenzae are unable to synthesize protoporphyrin IX (the immediate precursor of heme, an essential factor for many bacterial metabolic functions) from δ aminolevulinic acid. Thus, *H. influenzae* have an absolute requirement for exogenous heme (also known as factor X) for growth. In addition, they require nicotinamide adenine dinucleotide, or NAD (also known as factor V), for growth. In the laboratory *H. influenzae* grow best in complex media containing factors X and V (such as chocolate agar) under aerobic or facultatively anaerobic conditions at 35–37°C. Many strains show improved growth in 5–10% CO_2.[60]

4.2. Natural Competency

H. influenzae, like the other respiratory pathogens *S. pneumoniae* and *Neisseria*, are naturally competent; they possess specific mechanisms to acquire DNA from the environment.[68] Bacterial cells made competent during stationary growth phase are able to bind and absorb double-stranded DNA to their surface through the agency of the 9 base pair DNA uptake signal sequence 5'-AAGTGCGGT-3',[69] of which 1464 copies are randomly scattered across the *H. influenzae* genome.[70] After entering the cytoplasm, the donor DNA becomes single stranded and, upon hybridization with complementary bases on the recipient DNA, is incorporated into the host chromosome by homologous recombination.[71]

4.3. Genetic Variability

In adapting to its limited ecologic niches in the human pharynx, *H. influenzae* rely on fitness selection and clonal expansion of those population members that express the phenotypic characteristics important for survival in a particular human niche.[72] The sources of selective pressure that drive genotypic, and thus phenotypic, diversity among various populations of *H. influenzae* include host immune responses,[73] nutritional resources in the various microenvironments of the human respiratory mucosa[74] or blood stream,[75] and host factors necessary for bacterial adherence,[76] cellular penetration,[76] and host-to-host transmission.[77] The following genetic mechanisms alter either *H. influenzae* gene expression or gene content and generate organisms with fitness characteristics optimal for survival under various selective pressures, thus allowing the bacteria to adapt to rapidly changing microenvironments.

4.3.1. Genome Sequence. In 1995, the DNA sequence of the full genome of *H. influenzae* strain Rd (a multi-passaged, type d strain that had spontaneously lost expression of its capsule) was reported.[8] This genome was slightly over 1.8 million base pairs in size, with 1743 predicted coding regions. Importantly, several known virulence genes of *H. influenzae* were not present in strain Rd, such as those encoding haemagglutinating pili, Hap, and the high molecular adhesins HMW. Since then, complete or partial sequence information has become available for an increasing number of *H. influenzae* strains; complete sequences are deposited in the NCBI Web site: http://www.ncbi.nlm.nih.gov/sutils/genom_table.cgi: Comparisons of the genes in these genomes reveal considerable differences in gene content between the strains; 280 open reading frames were identified in strain 86-028NP that were absent from the Rd genome.[78]

4.3.2. Mechanisms of Genetic Diversity. A major theme in the biology of respiratory pathogens, including *H. influenzae*, is antigenic diversity, and several genetic mechanisms facilitating antigenic diversity of *H. influenzae* have been elucidated, including the following.

4.3.2.1. DNA Point Mutations. Mistakes in DNA replication that result in single base pair mutations in the *H. influenzae* genome create gene polymorphisms that may alter the immunologic, and occasionally the functional, character of proteins encoded by the mutated genes. The vast majority of spontaneous DNA mutations are detrimental to the bacterial cell and do not promote increased bacterial fitness and survival.

4.3.2.2. Presence or Absence of Coding Regions. Comparison of the gene content of the sequenced NTHi strains demonstrates as much as 25% variation.[79, 80] These changes represent loss or gain of genetic loci through spontaneous deletions or acquisition of bacterial genetic material through DNA uptake and homologous recombination into the *H. influenzae* genome.

4.3.2.3. Horizontal Gene Transfer. *H. influenzae* are naturally competent and, thus, capable of taking up environmental DNA and incorporating it into the bacterial chromosome by homologous recombination. As a result, "mosaicism," the apparent mixing and matching of genetic elements from various NTHi strains, occurs. Horizontal transfer of the *H. influenzae* P2 gene (which encodes an outer membrane protein), the *fts* gene (which encodes penicillin binding protein 3), and a specific capsule locus deletion between *H. influenzae* strains has been demonstrated.[81–84]

Acquisition of DNA from non-*Haemophilus* sources results in regions of *H. influenzae* with codon usage that reflects the donor DNA rather than native *H. influenzae* DNA. Sixty so-called putative aliens, loci with significant codon usage deviations from the average *H. influenzae* genome, have been identified in the Rd genome.[85] An example of non-*Haemophilus* DNA acquisition is the intergenic lateral transfer of tryptophanase gene cluster between *E. coli* and *H. influenzae*.[85]

4.3.2.4. Phase Variation. Expression of a number of gene products in *H. influenzae* is turned off and on through the agency of tandem repeat loci (referred to as microsatellites or contingency loci) in either the promoter regions or the coding regions of the genes. While these loci may contain repeats of 2–11 base pairs, most consist of tetranucleotides[57]; between 2 and 57 repeats have been reported. Because of the instability of the repeats, slipped strand mispairing occurs, which alters the numbers of DNA repeats present. As a result, the coding region is in or out of frame, resulting in high-frequency, stochastic, heritable genotypic switching of expression or modulation of transcription.[86] Examples include the contingency loci associated with genes that encode hemagglutinating pili, lipooligosaccharide (LOS)-modifying proteins, high molecular weight (HMW) adhesins, and heme-haptoglobin binding proteins[87–89] as well as additional genes of unknown function.[57] Phase variation is thought to be driven by changes in environmental conditions[90] and is considered a mechanism for immune evasion.[91]

4.3.2.5. Hypermutability. Most bacteria in a population are constrained in their ability to mutate, and deleterious mutations are much more common than beneficial mutations. The presence of a few bacteria in a population that are capable of frequent mutations provides the population with organisms that may be suited for survival during a sudden change in environmental conditions.[86] Many hypermutable organisms have defects in genes that encode components of the methyl-directed mismatch repair (MMR) system. In *H. influenzae,* hypermutable strains were found to have a mutation in *mutS* and to be more prevalent among strains isolated from the respiratory tracts of patients with cystic fibrosis, occurring in 14.5% of isolates,[92] than from other disease states.[93]

4.3.2.6. Allelic Variation. Minor changes in DNA sequence of *H. influenzae* virulence genes may alter their function. Sequence variants of *hmwA*, which encodes the high molecular weight adhesin, demonstrate variable binding characteristics to different epithelial cell receptors.[94] In addition, variants of *lpsA* (which encodes a glycosyl transferase) have been shown to add either glucose or galactose to *H. influenzae* LOS, and variants in the 3' end of the gene direct the anomeric linkage of the added hexose.[95]

4.4. Antibiotic Resistance

Like all bacteria, *H. influenzae* may possess genes associated with resistance to antimicrobial agents commonly used to treat infections caused by this agent. The resistance of *H. influenzae* to ampicillin and other β-lactam antibiotics is generally limited to either the production of a β-lactamase, with resultant enzymatic hydrolysis of the β-lactam-containing antibiotic, or the presence of altered penicillin binding proteins on the bacterial surface that exhibit lowered affinity for β-lactam antibiotic binding. Susceptibility of *H. influenzae* to all β-lactam antibiotics is generally predicted by susceptibility to ampicillin as defined by the Clinical and Laboratory Standards Institute (CLSI) MIC breakpoints, which are as follows: ≤ 1 μg/ml = susceptible, 2 μg/ml = intermediate, and ≥ 4 μg/ml = resistant.[96]

Resistance to ampicillin emerged in the 1970s, with the recognition of TEM-1 type β-lactamases, and has increased since that time,[97] with emergence and spread of additional β-lactamases, including ROB-1 β-lactamases and uncharacterized, novel β-lactamases. Prevalence of β-lactamase-producing strains varies widely by geographical area, ranging from 3% in Germany to 65% in South Korea.[98] Resistance prevalences also fluctuate over time, with US strains showing 36% β-lactamase-positive strains in 1994 compared to 26% in 2002.[99]

Ampicillin resistance in the absence of β-lactamase production was first described in the early1980s in type b and in non-encapsulated strains.[100,101] In these β-lactamase-negative, ampicillin-resistant (BLNAR) strains, nucleotide substitutions in the penicillin binding outer membrane transpeptidase PBP3 lead to reduced β-lactam antibiotic binding to the bacterial surface,[97] with MICs of 1–4 μg/ml. The prevalence of BLNAR strains varies worldwide and is seen in 40% of strains in Japan and 10% in Europe but $<5\%$ in the United States.[102]

Because plasmid-mediated TEM-1 and ROB-1 β-lactamase genes are located on transposons (i.e., Tn1), this type of antibiotic resistance may be transmitted between bacteria. In contrast, β-lactamase-negative, ampicillin resistance has arisen spontaneously among *H. influenzae* strains, with little evidence of clonal spread,[103] except for limited spread of specific BLNAR clones in patients with cystic fibrosis, between outpatients attending a single hospital, and between parents, children, and siblings.[97]

H. influenzae may be intrinsically resistant to macrolide-lincosamide-streptogramin B agents and ketolides and tetracyclines because of the action of efflux pumps; resistant to chloramphenicol through the production of plasmid-mediated production of chloramphenicol acetyltransferase;

and resistant to trimethoprim-sulfamethoxazole because of increased production of the enzyme dihydrofolate reductase.[97] Quinolone resistance among *H. influenzae*, due to alterations in DNA gyrase or topoisomerase IV genes, has been described and an outbreak with a levofloxacin-resistant strain has been reported in a long-term care facility.[104]

5. Descriptive Epidemiology

5.1. Epidemiology of Infections Caused by Type b *H. influenzae* (Hib)

5.1.1. Classical Hib Epidemiology in Non-immune Individuals. Prior to the introduction of the Hib vaccines in 1985, Hib was the most common cause of meningitis in young children in the United States. As recorded by Fothergill and Wright in 1933[4] and continues in many non-vaccinated populations, Hib infections occur rarely in the first 2 months of life because neonates are protected by placental passage of maternal anti-type b capsular antibodies. The peak age in unvaccinated children is 6–8 months,[105,106] with approximately 50% of cases occurring prior to age 12 months. The incidence falls during early childhood, with low incidence in children older than age 24 months, when naturally occurring antibody against the type b capsule begins to appear.

Before the use of the Hib vaccines, approximately one child in 200 (incidence between 40 and 100 cases/100,000 in the United States) developed Hib disease by age 5 years.[107] Among unimmunized children within the United States, certain racial/ethnic groups are at increased risk of invasive Hib infections, including American Indians[108,109] and Native Alaskans,[110] with incidence rates between 200 and 1000 cases/100,000. These high rates may be explained by living in large households under crowded conditions.[111,112]

Hib meningitis shows a bimodal seasonal pattern, with peaks between March and May and in October and November.[107] In most studies, no gender differences in Hib infections are seen.

5.1.2. Current Hib Epidemiology, US Children. With the introduction of the conjugated Hib vaccine in 1987, the epidemiology of *H. influenzae* type b infections changed dramatically (Figure 3). Recent data confirm that few *H. influenzae* invasive infections occur in children in the United States, as documented by the Active Bacterial Core surveillance (ABCs) program sponsored by the Centers for Disease Control (Table 3), or in individuals of all ages, as documented by the National Notifiable Diseases Surveillance System (Figure 4). Because of the variable capability for accurate serotype analysis in different laboratories, some of the strains of unknown type may actually represent type b strains.[9] Shortly after introduction of the vaccine, a strong herd effect related to vaccine protection was recognized[113] due to the vaccine's ability to reduce Hib colonization with subsequent interruption in person-to-person transmission, which contributes to the reduction in infections.

Similar to data collected prior to introduction of the vaccine, the highest rates of Hib disease in US children in 1994–1995 occurred among American Indian children, followed by African American and Caucasian children. Lowest rates occur among Asian/Pacific Islander and Hispanic children[114] (Table 4). The racial/ethnic discrepancies in these rates may be related to differences in vaccine coverage

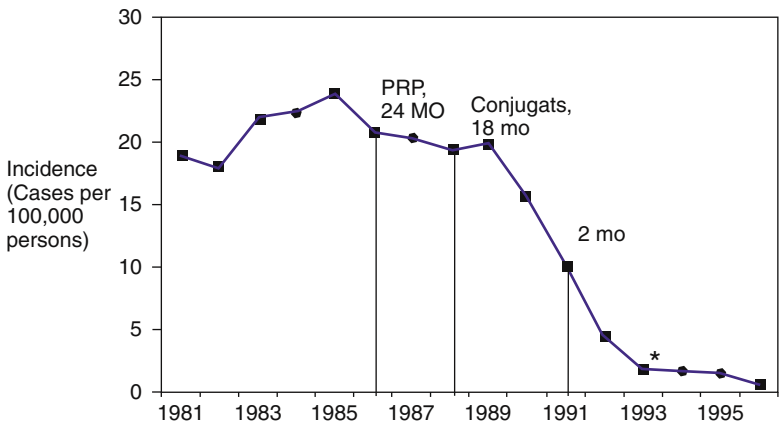

Figure 3. Hib meningitis in children less than 5 years old according to the National Bacterial Meningitis Reporting System, 1980–1991. Licensure dates and recommended ages of administration of PRP and conjugate vaccines are indicated (http://www.hhs.gov/nvpo/concepts/intro6.htm). * Active laboratory-based surveillance started, increasing sensitivity.

Table 3. *H. influenzae* Infections for Active Bacterial Core Surveillance Areas, 2006

Age (years)	Hib, # (rate)	Non-b, # (rate)	Non-typeable, # (rate)	Unknown type, # (rate)
< 1	2 (0.42/100,000)	10 (201/100,000)	31 (6.5/100,000)	4 (0.83/100,000)
1	0 (0.0)	4 (0.83/100,000)	3 (0.62/100,000)	1 (0.21/100,000)
2–4	3 (0.21/100,000)	5 (0.35/100,000)	12 (0.84/100,000)	1 (0.07/100,000)
5–17	1 (0.02/100,000)	3 (0.05/100,000)	13 (0.21/100,000)	1 (0.02/100,000)
18–34	0 (0.0)	6 (0.07/100,000)	22 (0.09/100,000)	7 (0.09/100,000)
35–49	1 (0.01/100,000)	15 (0.18/100,000)	37 (0.45/100,000)	11 (0.13/100,000)
50–64	4 (0.07/100,000)	29 (0.48/100,000)	53 (0.87/100,000)	15 (0.25/100,000)
>64	5 (0.12/100,000)	60 (1.5/100,000)	164 (04.1/100,000)	30 (0.75/100,000)

rates, in low socioeconomic status, in host susceptibility, or in high levels of Hib carriage in the population. The low level of Hib disease seen among children after the introduction of the Hib vaccine depends on maintenance of high post-immunization antibody titers among the age groups at greatest risk of invasive infections (those younger than age 5 years); failure to do so has resulted in re-emergence of increased rates of infections in the United Kingdom[115] and in Alaska (see Vaccine failures in Section 9.1.1). Among patients ≥6 months of age with Hib infection identified in the ABC surveillance program, 19 (17%) had unknown vaccination status, 31 (28%) were unvaccinated, 22 (20%) were undervaccinated, and 39 (35%) had completed the primary series.[116]

The mortality rate among 197 Hib cases reported in 1998–2000 through the ABC surveillance program[116] was 8%. Of these, 11 (79%) patients <6 months of age were unvaccinated and 3 (21%) patients >6 months of age were undervaccinated. Also similar to the pre-vaccine era, the most common types of Hib infection among children are bacteremia and meningitis.

In spite of high vaccine coverage in most of the United States, outbreaks of Hib disease still occur among poorly vaccinated populations. In Pennsylvania between December

* Per 100,000 population.

Table 4. Incidence of Hib Infections in US Children < age 4 Years by Race and Ethnicity, 1994–1995

Race/ethnicity	Hib, # (rate)	Unknown type, # (rate)
Non-Hispanic		
White	102 (0.40/100,000)	150 (0.59/100,000)
Black	32 (0.55/100,000)	52 (0.89/100,000)
American Indian	10 (2.83/100,000)	3 (0.84/100,000)
Asian or Pacific Islander	3 (0.20/100,000)	6 (0.40/100,000)
Hispanic	7 (0.11/100,000)	31 (0.49/100,000)

1999 and February 2000, eight cases of Hib invasive infection occurred in unvaccinated children <5 years old and six from communities with lower Hib vaccination coverage and higher Hib carriage.[117] One objective of the Healthy People 2010 initiative of the Centers for Disease Control (http://www.healthypeople.gov) is to reduce the rate of type b disease in children <5 years of age to 0/100,000 through widespread use of the Hib vaccine.

5.1.3. Current Hib Epidemiology, US Adults. Among adults, the incidence rates are highest among those aged ≥65 years (Table 3),[118] most likely reflecting increased susceptibility due to immune senescence[119] and increased co-morbidities among older Americans that lead to increased susceptibility to bacterial infections in general. A 1996–2004 study from Illinois demonstrated that 56.6% of Hib infections occurred in adults, 16% among individuals 50–64 years old, and 27.6% among individuals ≥65 years old.[118] The relationship between childhood Hib vaccination and Hib disease rates in adults is underscored by the observation in the United Kingdom that increased rates of infection among children due to vaccine failure was associated with a subsequent increase in disease rates in adults.[120]

5.1.4. Hib Epidemiology Worldwide. Globally, Hib is estimated to cause 2–3 million cases of serious disease, notably pneumonia and meningitis, and 450,000 deaths in young children each year.[121] Most countries in the Americas, Western Europe, and Australia have high Hib vaccine coverage and low incidence of infection. Vaccine has not yet been introduced in most of Africa, the Middle East, the Far East, Eastern Europe, and Russia and the former Soviet Union countries. In these countries, Hib remains a major bacterial pathogen responsible for endemic meningitis.[122] The actual burden of disease in the Middle East and North Africa is difficult to assess, as surveillance systems are weak, data collection is sporadic, and bacteriologic confirmation of the etiologic agent in invasive infections is infrequent.

5.1.5. Risk Factors for Hib Infections. Among vaccinated populations, risk factors in children for invasive *H. influenzae* type b infections include failure to receive the complete Hib vaccine series, underlying immunodeficiency, sickle cell disease, and HIV-AIDS.[123] In non-vaccinated populations, risk factors include young age (ages 2 months to 5 years) and exposure to a person infected with Hib, such as occurs among households and in day care centers. Genetic variations in host immune responses to polysaccharide capsules may play a role in the development of an effective immune response to Hib and, thus, in altered susceptibility to infection.[124] In addition, preceding viral respiratory tract infections and episodes of acute otitis media are associated with the development of invasive Hib infections. Furthermore, environment factors that increase exposure of young children to Hib appear to contribute to increased infection, such as household crowding and presence of siblings.[112] In multiple studies, day care center attendance has been shown to be an independent risk factor.[125] Conversely, breast feeding has been shown to be protective against Hib infection.[107]

5.2. Epidemiology of Infections Caused by Types a, c–f *H. influenzae*

H. influenzae possessing non-b capsules, e.g., types a and c–f, cause invasive infections but at much lower rates than type b strains. Infection rates range from 0.05 to 2.1/100,000, with the highest rates occurring among infants <1 year of age based on data from the ABC surveillance program.[126] Among the five non-b capsular types, the majority of invasive infections are caused by types f (58%) and e (28%).[118]

A relatively high incidence of type a invasive infections has been reported among indigenous populations of North America. Since the advent of the type b vaccine, type a strains are now the most common serotypes seen among invasive *H. influenzae* infections, representing 24% of Alaskan strains and 89% of Northern Canadian strains.[127] Among Navajo and White Mountain Apache children <5 years old, from 1988 to 2003, the annual rate of type a infections in this population was 20.2/100,000 and types c, d, and f infections 4/100,000, with the predominant diseases being meningitis (50%) or pneumonia (27.6%).[42] Increased rates of a, e, and f invasive infections have not occurred with widespread use of the Hib vaccine (which has no effect in preventing infections with non-b strains); infections with types c and d occur too infrequently for a meaningful assessment of changing trends.[42,128] Thus, "sero-type replacement," such as has been seen with *S. pneumoniae* infections after introduction of the seven valent conjugate *S. pneumoniae* vaccine, apparently has not occurred following introduction of the Hib vaccines.

Pulsed-field gel electrophoresis (PFGE) analysis of *H. influenzae* type a isolated from 32 Navajo with invasive

infection showed them to be 90% similar using digestion with the restriction enzyme *Bln* I and 91% similar using digestion with *Sma* I. Control type a strains isolated from seven US or Canadian children showed 63 and 36% similarity, respectively,[42] suggesting limited genetic diversity of strains isolated on the Navajo reservation, in spite of the fact that they were isolated from geographically and temporally distinct cases.

Invasive infections in children with type a *H. influenzae* can be very severe, similar to those caused by type b strains. Genomic analysis of type a strains showed duplication of the *cap* region, similar to that seen in Division I Hib strains.[129] Furthermore, several had the same partial deletion of one of the *bexA* genes as seen in type b strains, which is thought to stabilize the duplication and result in increased capsule production and virulence.[84] Examination of other non-b, encapsulated *H. influenzae* revealed single copies of the *cap* region in types c and d strains, but types e and f strains contained duplicated copies, some with the *bexA* deletion in one copy.[130]

5.3. Epidemiology of Infections Caused by Non-typeable *H. influenzae*

The rate of NTHi invasive infections among all age groups, as identified in the Active Bacterial Core surveillance (ABCs) network, is 0.95/100,000 individuals. The highest rates are in children <1 year of age and adults >65 years (Table 3). NTHi sepsis among newborns, which is estimated to occur in 1.6–1.9/100,000 live births,[131] is associated with maternal peripartum infections[132] and infant prematurity.[133] Among adults, most NTHi invasive infections are associated with a variety of acute and chronic medical conditions.[134,135] Since the Hib vaccine protects only against infections caused by type b organisms, this vaccine has no impact on the epidemiology of non-typeable *H. influenzae* infections.

Systematic surveys of non-invasive non-typeable *H. influenzae* infections are not available but have been reported in the context of clinical studies. Eskola et al.[136] reported rates of *H. influenzae* acute otitis media to be 203 episodes/1000 children/year among healthy Swedish children under 18 months of age. Interestingly, these rates were lower than those of healthy children who received the seven-valent *S. pneumoniae* conjugated vaccine (283 episodes/1000 children/year), suggesting that altered pharyngeal flora following *S. pneumoniae* conjugated vaccine resulted in increased *H. influenzae* otitis media.

Occasional outbreaks of non-typeable *H. influenzae* have been reported, primarily associated with nursing homes[137,138] or respiratory rehabilitation units.[139,140]

6. Mechanisms and Routes of Transmission

Because *H. influenzae* live exclusively in humans, person-to-person transmission is vital to survival of these bacteria. The organisms are spread via infected respiratory droplets and establish colonization in the upper respiratory tract (the naso- and posterior oro-pharynges). Murphy et al.[141] demonstrated that Hib in nasal secretions were able to survive up to 18 h on tissue paper, wax paper, and dry gauze. Hib could not, however, be isolated from swab cultures of fomites in day care settings known to be exposed to children carrying Hib. Hib is recovered in higher titers and for longer duration from laminated or steel surfaces than from porous surfaces such as paper or cloth and the recovery is improved with higher inocula.[142] To reduce the potential for transmission of Hib among hospitalized patients, respiratory isolation precautions are recommended for patients with *H. influenzae* type b infections for 24 h after initiating appropriate antibiotic therapy.

Molecular epidemiologic tools (see Section 3.2.2) allow tracking the transmission of *H. influenzae*. Strains isolated from family members show high genetic similarity, suggesting intrafamilial spread.[38,143,144] A single genotype of non-typeable *H. influenzae* may be found in multiple children attending a day care center, demonstrating transmission within day care.[34,35,145]

Environmental factors directly related to transmission of *H. influenzae* in humans are difficult to identify, but factors associated with sharing of genotypically identical NTHi in day care centers may serve as a marker of transmission. Such factors include a higher number of children in the day care center, suboptimum hygiene habits, and pacifier use.[146]

Bacterial factors may also be important in person-to-person spread of *H. influenzae*, but have not been clearly identified. Transmission factor candidates include absence of adhesins or adhesin variants that lose the ability to adhere to certain epithelial cells.

7. Pathogenesis and Immunity

7.1. *H. influenzae* Colonization

With rare exceptions, *H. influenzae* exist exclusively in the upper respiratory tracts of humans where they live as asymptomatic commensals. As such, colonization of the host's pharynx is the first step in the pathogenesis of any *H. influenzae* infection.

7.1.1. Colonization with *H. influenzae* Type b (Hib). Pharyngeal colonization with type b organisms in non-immune individuals is relatively rare, with point prevalence rates ranging from 0.7 to 5.3%.[147] Cumulative (over

18 months) prevalence rates of Hib carriage among children in day care, however, were between 48 and 71% in toddlers and preschool age children, with lower rates among infants and adults and school age children,[148] demonstrating that over time, many unimmunized children may be colonized with Hib. Introduction of conjugate Hib vaccines has further reduced carriage of Hib in young children[149]; the appearance of a herd effect among vaccinated populations suggests that reduced colonization rates extend beyond those children who are immunized.[113]

7.1.2. Colonization with Non-typeable *H. influenzae* (NTHi). Asymptomatic colonization with non-typeable *H. influenzae* in healthy children is extremely common, with point prevalence rates of approximately 25 to 77–84%[34,150–154]; the wide variability may be related to differences in the populations studied and in culturing techniques.[35] Colonization with non-typeable *H. influenzae* begins early in life, increases in frequency during childhood, and then decreases during adolescence and adulthood.[155,156]

Recent studies have demonstrated that NTHi colonization, as determined by bacterial culture of respiratory samples, is a very dynamic process, characterized by rapid bacterial turnover[152,157,158] and carriage of multiple NTHi strains at any one time.[150,159–162] Multiple *H. influenzae* genotypes are frequently present in the upper respiratory tracts of adults with cystic fibrosis,[92] of adults with chronic obstructive pulmonary disease,[161] and of children in day care centers.[34,35] Studies from healthy children attending day care demonstrated a 62% turnover rate of *H. influenzae* isolates from week to week, and 37–43% of throat cultures contained two or more genetically distinct NTHi (range = 0–5).[34,35] A study of chronic carriage in four healthy adults over 7 months showed carriage with multiple genotypes over time, co-colonization with several genotypes at a single point in time, intermittent recovery of individual genotypes, and prolonged carriage (up to at least 198 days) with a single genotype.[36] The best explanation for this dynamic pattern of colonization is the presence of a large population of organisms colonizing the respiratory tract, with ongoing evolution of the organisms and acquisition and loss of specific genotypes.

Risk factors associated with asymptomatic NTHi colonization include exposure to tobacco smoke[146,151,163] and attending day care.[145] In the day care setting, risk factors include ≥5 classrooms in the center and suboptimal hygiene practices such as minimal handwashing by staff after eating and by children after wiping their own noses.[146]

7.1.3. *H. influenzae* and Biofilms. Growing evidence confirms that *H. influenzae* inhabit mucosal surfaces as biofilms[164,165] and several *H. influenzae* bacterial factors have been shown to be important in biofilm formation, including presence of hemagglutinating pili[166] and type IV PilA,[167] and sialylation of lipooligosaccharides.[168] Bacteria growing in a biofilm are in a different metabolic state than those grown under planktonic conditions and thus exhibit different phenotypic characteristics; for example, the expression of lipooligosaccharide is altered during NTHi growth in a biofilm.[166] The observation that biofilm growth increases the phosphorylcholine content and decreases the potency of non-typeable *H. influenzae* endotoxins suggests a mechanism for reduced mucosal inflammation during colonization compared to infection.[169]

7.2. *H. influenzae* Virulence Factors

While *H. influenzae* asymptomatically colonize the human pharynx, they cause infection and disease at other body sites. These bacteria, like other pathogens, possess a number of factors that facilitate its pathogenicity in humans, such as factors that allow the bacteria to adhere to mucosal surfaces and promote colonization, that evade the host's immune system, that degrade host protective factors, and that stimulate an inflammatory response in the host that then causes the symptoms of the disease.

7.2.1. Polysaccharide Capsule. The most important virulence factor associated with pathogenic *H. influenzae* is the type b capsule, which is carried by the majority of *H. influenzae* strains that cause invasive infections such as bacteremia, meningitis, septic arthritis, cellulitis, and epiglottitis. Strains carrying types a and c–f capsules also cause invasive infections, but their incidence is much lower than that of type b infections in non-immune populations. The type b capsule protects the bacteria from phagocytosis by interfering with the binding of complement and opsonizing antibodies to the bacterial surface.[170] In addition, the strong negative charge of the polysaccharide capsule may provide electrostatic repulsion to phagocytic cells.[171]

7.2.2. Attachment Factors. *H. influenzae* possess a number of adhesins that facilitate bacterial adherence to epithelial cells and the respiratory mucosa and, thus, facilitate colonization, the initial event in the pathogenesis of *H. influenzae* infection and disease.

Hemagglutinating pili are complex, filamentous structures that extend from the bacterial surface and are antigenically very diverse.[172,173] Expression of pili is phase variable and expression occurs more commonly on bacteria isolated from mucosal surfaces than from sites of invasive infection. Adherence is mediated through the HifE proteins, which are located at the tips of the pili[174] and appear to bind to sialic acid-containing lactosylceramides on cell surfaces.[175]

High molecular weight adhesins (HMW) are present only in non-typeable *H. influenzae*. These proteins show high sequence diversity and bacteria that express certain allelic forms have different binding affinities for transformed epithelial cells.[94] HMW expression is also phase variable[88] and variants lacking the *hmw* genes are more prevalent among strains isolated from throat specimens than from middle ear specimens, suggesting the role of HMW in the pathogenesis of acute otitis media.[176,177]

Hia is a surface adhesin found primarily on non-typeable strains that do not express HMW. The protein is homologous with Hsf, also known as fibrils, found on type b strains.[178]

The serine protease Hap, another surface adhesin, is structurally but not functionally related to IgA protease and undergoes autoproteolysis with release of the adhesive region, Hap_s. The protein self-assembles into fibrillar structures that bind to each other, facilitating the formation of bacterial microcolonies.[179] In addition, host-mediated inhibition of the autoproteolysis results in retention of the central protease region on the bacterial cell surface, which facilitates adherence of the bacteria to respiratory epithelial cells.

P5 (also known as P5 fimbrin) are thin fibillae-like structures that mediate adherence to the carcinoembryonic antigen family of surface proteins on respiratory cells.[180] P5 proteins have been demonstrated to exhibit antigenic drift during the process of human colonization with *H. influenzae*.[181]

Several additional adhesins have been described from *H. influenzae* and include lipooligosaccharides,[182] the opacity-associated protein OapA[183] and the type IV pilus adhesin PilA.[184]

7.2.3. Lipooligosaccharide (LOS). *H. influenzae* lipopolysaccharides lack the O-specific side chain found in enteric gram-negative bacteria and, thus, are termed by many investigators lipooligosaccharides (LOS). They have been shown to be important determinants of virulence in animal models of bacteremia.[185] The core LOS structure is a short oligosaccharide composed of three conserved heptoses, which may be modified with a variety of carbohydrate moieties (such as glucose, galactose, or heptulose) and non-carbohydrate moieties (such as phosphoethanolamine, phosphocholine, sialic acid, and glycine).[186] Many of the glycosyl transferases responsible for LOS modifications are phase variable, contributing to the widely variable structure of *H. influenzae* LOS.[187]

One LOS modification, the addition of phosphatidylcholine (ChoP), has been associated with acute otitis media in the chinchilla model.[188] While strains expressing ChoP are commonly found among pharyngeal commensal strains,[189] most invasive strains do not express this LOS modification,[190] suggesting its role in colonization and not in disease. This suggestion is corroborated by the observation that ChoP expressing *H. influenzae* are more susceptible to C-reactive protein-mediated serum killing.[189]

Another LOS modification, the addition of sialic acid, also confers serum resistance to *H. influenzae*.[191] Sialic acid is a common surface constituent of human cells and its presence on *H. influenzae* may protect the bacteria from the host immune system through molecular mimicry. Additional modifications involving the glycosyl moieties and O-acetylation of LOS result in increased serum resistance and increased virulence of *H. influenzae*.[186]

H. influenzae LOS appears to stimulate an innate immune response in the human host through interactions with Toll-like receptor 4 (TLR4),[192] presumably thus activating the NF-κB pathway. As a result, a variety of inflammatory molecules are produced, including IL-6, IL-8, TNFα, and MCP-1.[193]

7.2.4. Iron and Heme Uptake. Because *H. influenzae* has an absolute growth requirement for iron, as supplied by exogenous heme, the organism has several, possibly redundant and/or complementary, mechanisms for the acquisition of iron from heme and related iron-containing compounds. Hgp proteins are encoded by a group of four (*hgpA-D*) phase-variable genes and are involved in the utilization of heme from both hemoglobin and hemoglobin:haptoglobin complexes. Different strains of NTHi contain between one and four *hgp* genes. Mutant NTHi strains lacking all *hgp* genes showed reduced virulence in a chinchilla model of otitis media as compared to wild type[194] as well as reduced ability to initiate and sustain type b bacteremia in weanling rats.[195] The *hux* operon, consisting of three genes, encodes proteins important in binding heme and heme:hemopexin. A mutant Hib strain lacking *hxuA-C* produced lower bacterial titers during bacteremia, with associated improved survival rates, in 5-day-old rats as compared with the wild-type strain.[196]

Other iron metabolism factors, such as the heme-binding lipoprotein HbpA, transferrin binding proteins Tbp1 and Tbp2, and the hemin receptor HemR deserve further study as potential virulence factors of *H. influenzae*. Epidemiology-based prevalence studies of potential Hi virulence factors have shown that *hgpB* (encoding hemoglobin binding protein) and *hemR* (encoding hemin receptor) are present in 100% of *H. influenzae* isolated from infections in the middle ear and only 70 and 83%, respectively, in commensal strains isolated from the throats of healthy children[177] suggesting their potential role in acute otitis media.

7.2.5. IgA Protease. IgA protease is an endopeptidase that inactivates the immunoglobulin IgA1 by enzymatic

cleavage. Although all *H. influenzae* strains possess *iga*, the gene has high sequence variability between strains. Nontypeable *H. influenzae* isolated from infected patients have significantly higher levels of IgA1 protease activity than strains isolated from asymptomatic carriers.[197]

7.2.6. Other Virulence Factors. Additional virulence factors of *H. influenzae* include protein D, a highly conserved lipoprotein that compromises the mucociliary escalator in respiratory cells in tissue culture[198] and has been shown to induce otitis media in a rat model.[199] Furthermore, Sap proteins, which confer resistance to antimicrobial peptides in the respiratory tract, contribute to acute otitis media in chinchillas.[200] LuxS, involved in the quorem-sensing activity of gram-negative bacteria, has also been shown to modulate acute otitis media in chinchillas.[201]

7.3. Immunity

The relationship between immunity, as defined by the ability of blood samples taken at various ages to kill *H. influenzae* type b bacteria in vitro, and protection against infection with *H. influenzae* type b has been recognized since the landmark studies of Fothergill and Wright in 1933,[4] Figure 5. Subsequently, the major component of the protective factor in blood has been shown to be antibodies against the type b capsule. As a result of these studies, vaccines, composed first of the purified type b capsule and later of the purified capsule conjugated to a carrier protein, have been developed and have nearly eliminated type b disease in populations with high vaccine use (see Section 9.1.1, Type b *H. influenzae* vaccines). The success of vaccines containing the purified capsule of *H. influenzae* underscores the important role of immunity to the type b capsule in protecting against disease. Immunity against a variety of additional *H. influenzae* surface structures, particularly those of nontypeable strains, has also been well studied in work directed at developing additional *H. influenzae* vaccines (see Section 9.2, Vaccines against NTHi).

7.3.1. Immunity Against the Type b Capsule. The type b capsule of *H. influenzae* is a complex carbohydrate composed of repeating units of polyribosyl ribitol phosphate or PRP. Natural immunity against *H. influenzae* type b develops in healthy humans during early childhood and is the result of natural antibodies directed against the type b capsule, among other possible antigens. The antigenic stimuli for the development of natural anticapsular antibodies is unclear, but may be related to asymptomatic pharyngeal colonization with type b *H. influenzae* or colonization with bacteria that possess cross-reacting capsular material, such as *E. coli* K100, *S. aureus*, *Bacillus pumilus*, *Lactobacillus plantarum*, or *Streptococcus faecium*.[202,203]

7.3.1.1. Age-Related Capsular Immunity. Relatively high levels of antibodies directed against the capsule of *H. influenzae* are present at birth because of transplacental transfer of maternal antibody to the fetus. These antibodies are degraded shortly after birth and fall to undetectable levels by age 6 months. Subsequently, the levels rise again as natural antibodies are generated and adult levels are achieved in most children by age 5 years.

Many young children under age 2 years are unable to generate an antibody response to purified capsular polysaccharides, including the PRP of *H. influenzae* even following systemic infection with Hib.[204] With increasing age and maturation of their immune systems, many children over age 2 years generate a brisk antibody response to antigenic stimulation with the type b capsule, either through infection with *H. influenzae* type b or through vaccination with purified PRP.

7.3.1.2. Role of T Cells in Capsular Immunity. Failure of young children to illicit a protective and enduring antibody response to purified type b capsule antigen is a function of the immaturity of their immune systems and their limited ability to activate T-helper cells upon exposure to purified polysaccharide antigens. T-helper cells are important in the maturation, differentiation, and proliferation of B cells that produce specific antibody. Thus, young children under age 2 years illicit a T-independent (i.e., thymus independent) response to purified polysaccharides, which is characterized by low levels of antibody, primarily IgM antibody with little IgG antibody, and poor immunologic memory that results in a short-lived, non-boostable immune response. On the other hand, most children over age 2 years are able to illicit a T-cell-dependent response to purified polysaccharide antigens in which activated T cells provide the appropriate immune signals to stimulate activation of B cells, resulting in the production of antibody that is long lasting and demonstrates an anamnestic response upon re-exposure, thus immune memory.[205]

To convert T-cell-independent *H. influenzae* capsular polysaccharides to T-cell-dependent antigens, the purified PRP capsule has been chemically conjugated to several different protein carriers, including diphtheria toxoid; CRM_{197}, a nontoxic derivative of diphtheria toxin; OMP, an outer membrane protein of group B *N. meningitidis*; and tetanus toxoid (see Section 9.1.1, *H. influenzae* type b vaccines). The carrier proteins permit polysaccharide interactions with T cells to provide appropriate immune signals necessary to generate a T-cell-dependent response that stimulates B-cell proliferation, differentiation, and antibody production. These conjugated PRP antigens stimulate high levels of anticapsular antibodies in children as young as 2 months of age that persist for extended periods of time and show an anamnestic (memory) response upon boosting.

Figure 5. The relationship of age of *H. influenzae* type b meningitis to the bactericidal power of human blood against Hib at various ages.[4]

7.3.1.3. Biologic Activities of Capsular Antibodies. Antibodies against the type b capsule provide host protection against infection through several different mechanisms, including activation of complement, complement-mediated opsonophagocytosis, and direct, complement-mediated bacterial lysis.[206] Serological correlates of protection for type b antibodies have been estimated to be 0.15 μg/ml of anti-PRP antibody based on protective levels in adult sera[207,208] and 1 μg/ml of anti-PRP antibody based on post-vaccination levels that offered protection for a year[209] (see Section 9.1.1.2, Serologic correlates of immunity).

7.3.1.4. Mucosal Immunity. The role of mucosal antibodies in protection against *H. influenzae* infection remains unclear. Secretory IgA anticapsular antibodies are present in mucosal secretions of children following *H. influenzae* infection or vaccination with the Hib polysaccharide vaccine.[210–212] IgA antibodies, however, do not bind complement and, thus, are thought to lack bactericidal activity against *H. influenzae*. Their role, rather than bacterial killing, may be to impair adherence of *H. influenzae* to respiratory tissues or to facilitate bacterial clumping with resultant increased clearance from the respiratory tract.

Although purified polysaccharide Hib vaccines appear to stimulate antibodies in respiratory secretions, either IgA or serum-derived IgG antibodies that are present in the secretions through transudation, immunity stimulated by these carbohydrate antigens does not reduce colonization of *H. influenzae* type b. On the other hand, the protein conjugated polysaccharides, including conjugated *H. influenzae* type b vaccines, stimulate antibodies that significantly reduce Hib colonization.[213]

In addition to adaptive, antibody-derived immunity, the innate immune system, which includes antimicrobial peptides present in the mucosa that lines the respiratory tract, also acts against respiratory pathogens. The cationic peptides β defensins[214] and the human cathelicidin LL37[215] as well as lysozyme[216] appear to bind to various components of *H. influenzae* lipooligosaccharides, resulting in bacterial cell death.

7.3.2. Immunity Against Non-capsular Antigens. The success of the Hib vaccines in reducing *H. influenzae* type b disease clearly emphasizes the importance of capsular antibodies in providing protective immunity against *H. influenzae* type b. The importance of immunity against non-capsular antigens in providing immune protection against *H. influenzae* disease is less clear. Many surface proteins stimulate antibodies in humans[217] that exhibit bactericidal and/or opsonophagocytic activities but their role in protection against disease is difficult to discern, in part because of significant antigenic variation among many of the surface proteins.[89] The use of the chinchilla model of *H. influenzae* has been valuable to define the ability of

non-capsule antigens to stimulate immune protection, which is often partial protection, to prevent acute otitis media.[218]

8. Patterns of Host Response

8.1. Infections with Typeable *H. influenzae*

8.1.1. Diseases Caused by Encapsulated *H. influenzae*. Prior to the introduction of the type b vaccine, type b *H. influenzae* was the most common cause of bacterial meningitis in children in the United States. In addition, type b strains commonly caused epiglottitis, bacteremia, septic arthritis, periorbital and facial cellulitis, and pneumonia. Less common manifestations of invasive type b *H. influenzae* include osteomyelitis, pericarditis, endocarditis, epididymitis, endophthalmitis and peritonitis. *H. influenzae* expressing the other capsular types, a, c, d, e, and f, also cause occasional invasive infections such as bacteremia and meningitis.

Bacteremia with encapsulated *H. influenzae* almost always precedes *H. influenzae* infections at distal sites and is the means by which the bacteria access meninges, joints, pericardium, and other tissues. In non-immune children, Hib bacteremia without focus is a relatively common illness, which presents with fever and no localizing symptoms of infection. While *H. influenzae* bacteremia without focus may spontaneously resolve with no residual clinical sequelae, it may result in Hib seeding of distant tissues, commonly the meninges.

Bacterial meningitis, including that caused by encapsulated *H. influenzae*, is an extremely serious, acute infection of the membranes surrounding the brain and spinal cord. Early symptoms include fever, lethargy, and irritability and later symptoms include vomiting, stiff neck, and seizures. Children with symptoms suggestive of bacterial meningitis require immediate medical care to diagnose and appropriately treat this infection. Mortality rates approximate 5–10% and morbidity includes mental retardation, blindness, hearing loss, and persistent seizures.

In non-immune individuals, *H. influenzae* type b is the predominant cause of epiglottitis (infection of the epiglottis) which presents with fever and rapidly progressing, severe respiratory distress from upper airway obstruction. Hib is also a significant cause of septic arthritis, which presents with fever and joint swelling accompanied by redness of the overlying skin. Facial cellulitis is an infection of infants that is nearly always caused by *H. influenzae* type b and is characterized by fever and rapidly developing swelling of the skin of the face with redness that progresses to purple discoloration.

All cases of *H. influenzae* invasive disease, including type b and non-type b, should be reported to the Centers for Disease Control and Prevention through the appropriate local or state public health departments.

8.1.2. Mechanisms of Disease Caused by Encapsulated *H. influenzae*. Type b, and to a lesser extent non-b encapsulated *H. influenzae*, gain access to the blood stream by unknown mechanisms, circulate, and seed various organs, such as meninges, skin, pericardial or pleural spaces, and joints. Type b strains are thought to directly seed the epiglottis, and possibly the lower respiratory tract, from the pharynx. All forms of infection with encapsulated *H. influenzae* are associated with bacteremia, either as a primary or a secondary event.

The most important virulence factor for invasive *H. influenzae* disease is the type b capsule, which differs chemically and antigenically from the capsules of the other encapsulated *H. influenzae*. The mechanisms of type b capsule-mediated *H. influenzae* virulence include resistance to phagocytosis because of the strong negative charge of the capsule and resistance to complement-mediated bacterial lysis. In most type b strains, the capsule in encoded by a duplicated *cap* gene region with a 1.2 kb deletion in one of the *bexA* genes.[219] Up to five copies of the *cap* region has been described in invasive Hib strains and increased copy number has been correlated with increased capsule elaboration[220] and with decreased susceptibility of the bacteria to both complement-mediated lysis and opsonization.[221] Invasive strains of type a *H. influenzae* have also shown the partial *bexA* deletion, suggesting an explanation for their virulence.[222]

While the presence of the type b capsule allows *H. influenzae* to survive during bacteremia, it is the host inflammatory response to the infection that is associated with the manifestations of the disease. Bacterial factors other than capsule, for example lipooligosaccharides, stimulate inflammatory cytokines such as Il1β and TNFα[223,224] that lead to the symptoms associated with infection.

8.2. Infections with Non-typeable *H. influenzae* (NTHi)

H. influenzae that lack capsular polysaccharides are phylogenetically unique from encapsulated *H. influenzae*,[23] with different outer membrane protein patterns.[225] While NTHi strains are highly diverse, well-defined phylogenetic groups that differ in gene content have been identified using MLST but these groups do not correlate with NTHi diseases.[226]

8.2.1. Diseases Caused by NTHi. The majority of infections caused by non-typeable *H. influenzae*, which lack the polysaccharide capsule, in healthy individuals are limited

to the respiratory tract and include acute otitis media and sinusitis in children and pneumonia and bronchitis in adults. Since the introduction of the conjugated *S. pneumoniae* vaccine in children, NTHi has emerged as the major cause of acute otitis media, responsible for between 30 and 52% of these infections.[136] Furthermore, NTHi cause approximately a third of episodes of acute sinusitis.[227]

Community-acquired pneumonia, particularly in children in developing countries and among the elderly, is often caused by NTHI.[228,229] Non-typeable *H. influenzae* are the most commonly seen bacteria in acute exacerbations of chronic obstructive pulmonary disease (COPD)[230,231] and appear to contribute to COPD progression.[232] Acute exacerbation in COPD patients often occurs with acquisition of a new strain of *H. influenzae*, relative risk = nearly 3.0.[230]

In addition to persons with underlying bronchial and pulmonary chronic illnesses, patients with anatomic defects such as primary ciliary dyskinesia or patients with common variable immunodeficiency, IgA deficiency or IgG3 deficiency may have bronchitis or pneumonia caused by NTHi. Furthermore, non-typeable strains may rarely cause bacteremia and/or meningitis, particularly among individuals with underlying medical conditions such as cerebral spinal fluid leaks, prematurity, lymphoproliferative syndromes, or hypogammaglobulinemia.[233,234]

8.2.2. Mechanisms of Disease Caused by NTHi. The initial interaction of NTHi with a human host is adherence to the respiratory mucosal cells, thus establishing asymptomatic colonization of the pharynx. NTHi may, subsequently, gain access to the middle ear space from the pharynx by ascent through the Eustachian tube and subsequently initiate an inflammatory response resulting in acute otitis media.[235] In addition NTHi presumably gain access to the respiratory sinuses through the ostia that naturally provide egress of sinus secretions into the pharynx and, once established in the sinuses, cause acute sinusitis. In patients with damaged airways, such as those with cystic fibrosis or COPD, the bacteria descend from the pharynx into the bronchi where they may establish chronic infection.

While NTHi lack toxins and a capsule, which is the major pathogenic factor of type b *H. influenzae*, they possess a number of potential virulence factors that may contribute to disease, including adhesins, lipooligosaccharide, IgA protease, and other outer membrane proteins.[91] Interactions between NTHi and host cells through the Toll-like receptors TLR2 and TLR4 as well as the platelet-activating factor receptor PAFR have been shown to initiate intracellular signals through the mitogen-activated kinase cascade or by way of p38 activation that are involved in many human inflammatory pathways.[235]

8.3. Infections Caused by Unique *H. influenzae* Strains

8.3.1. Conjunctival Infections. Bacterial conjunctivitis (presenting with mucoid or purulent discharge from the eyes[236]) is often caused by non-typeable *H. influenzae*, occurring up to 40% in some series[237] with even higher occurrence in children.[238] The *H. influenzae* isolated from the eye exudates of these patients are genetically unique and appear to represent the bacterium originally observed by Koch[239] in pus from the eyes of patients with conjunctivitis in Egypt and cultured from cases of conjunctivitis in the United States by Weeks,[240] hence the term "Koch–Weeks bacillus." Originally designated *Haemophilus aegyptius*, these strains are very closely related to *H. influenzae*.[226,241] Several investigators suggest they do not belong to a separate species based on DNA hybridization studies[242] and on the observation that no one single feature differentiates the two organisms.[243,244] Thus, acute conjunctivitis isolates are often designated "*H. influenzae*, biogroup aegyptius."

Simultaneous presentation of conjunctivitis and acute otitis media, the so-called conjunctivitis–otitis syndrome, is strongly associated with isolation of *H. influenzae* from both sites. Pulsed field gel electrophoresis analysis of paired *H. influenzae* isolates from the conjunctival exudate and middle ear fluid of patients showed identical strains in each patient.[245]

8.3.2. Brazilian Purpuric Fever. In late 1994, 10 children in the town of Promissao in Sao Paulo State, Brazil, developed a severe illness characterized by high fever, abdominal pain and vomiting, hemorrhagic skin lesions, vascular collapse, and death. In the majority of affected children, the acute illness was preceded by an episode of acute conjunctivitis. This syndrome, called Brazilian purpuric fever, subsequently affected over a hundred children in Brazil and cultures of the blood or cerebrospinal fluid of several patients yielded non-typeable *H. influenzae* that were genetically related to *H. influenzae* biogroup aegyptius.[246]

The *H. Influenzae* strains associated with Brazilian purpuric fever (so-called BPF strains) are identical by a wide range of genotypic and phenotypic criteria[247] and resist killing by normal human sera.[248] In spite of extensive effort, no unique bacterial factor that underlies the profound virulence of this clone compared to other *H. influenzae* biogroup aegyptius strains has been identified.

8.3.3. Genital Infections. Although *H. influenzae* reside in the human respiratory tract and cause respiratory tract infections or occasionally bacteremia and invasive infections, a cryptic genospecies of non-typeable *H. influenzae* causes urogenital, puerperal, and neonatal infections.[249,250] These biotype IV strains have a unique outer membrane P6 protein[251] and are genotypically (as

assessed by MLEE) divergent from all other *H. influenzae* isolates.[23] 16S rRNA analysis has demonstrated that these genital strains are most closely related to *H. haemolyticus*, a species closely related to *H. influenzae* that has not been linked to human infection.[250]

9. Control and Prevention of *H. influenzae* Infections

9.1. Prevention of Type b Infections

9.1.1. Hib Vaccines. The polysaccharide of type b *H. influenzae*, polyribosyl ribitol phosphate (PRP), has many properties important as a vaccine antigen, including antigenic conservation among all type b strains, immunogenicity in humans, and induction of protection against Hib infection and disease. Thus PRP, licensed in 1985, was the first purified polysaccharide formulation used as an *H. influenzae* vaccine. Early studies of vaccines composed solely of the purified PRP demonstrated that children under age 2 years developed relatively low titers of serum antibodies that appeared insufficient to protect against invasive disease.[252] Antibody induced by purified PRP was found to wane quickly and immunization provided no immune memory.[253]

Based on the knowledge that polysaccharides conjugated to proteins stimulate enhanced immune responses and protective immunity in animals,[254] vaccines composed of purified PRP conjugated to a variety of protein carriers were developed,[255] Table 5.

The Hib conjugate vaccines differ in their immunogenicity, probably related to the nature of the carrier protein that acts as a hapten, and the method of coupling, either covalent linkage or chemical conjugation of the protein, to the polysaccharide. PRP-D is no longer used in young infants because of its poor immunogenicity and poor protection against Hib infection in Alaskan Native children, a population with a high level of natural disease.[256] PRT-T, PRP-OMP, and HBOC have all been shown to generate high levels of anti-PRP antibodies in infants and to be highly protective against Hib invasive infection.[257] Repeated administration of conjugate vaccines elicits booster responses, thus maximizing the level of the immune responses achieved.

9.1.1.1. Clinical Trials of Hib Vaccines. The large clinical trials designed to evaluate the efficacy of conjugate Hib vaccines used different strategies.[257] Classic double-blind placebo-controlled studies of PRP-D and PRP-OMP were conducted in Native American and Alaskan Native populations in which relatively small numbers of vaccine recipients were needed because of the high rates of Hib disease in the study populations. In contrast, PRP-D and HbOC were compared in trials in Finland, a population with relatively low levels of Hib disease, with estimates of efficacy based on historical data. A case–control study of HbOC was conducted in the United States in Los Angeles County, an area with relatively low coverage rates of the conjugated vaccine (PRP-D) licensed at that time.[258]

Because of the various study designs, comparing the efficacies of the vaccines is difficult. The only head-to head-comparison, PRP-D and HbOC, conducted in Finland with relatively low infection rates, showed no statistically significant differences in their efficacy.[259] The poor performance of PRP-D among Alaskan Natives is likely related to its poor immunogenicity, as trials of other conjugate vaccines in populations with high disease rates, PRP-T in Gambia[260] and PRP-OMP in Navajo Indians,[261] showed excellent vaccine efficacy.

9.1.1.2. Serologic Correlates of Immunity. The identification of levels of serum antibody that correlate with protection against vaccine-preventable infections is a keystone to understanding vaccine-induced immunity, as these correlates predict the efficacy of a vaccine against natural infection in the face of an average infecting dose of the bacteria.[262] Although mucosal and cellular immunity may have a role in protecting against *H. influenzae* infections, the presence of serum antibody directed at the type b capsule strongly correlates with protection. Several lines of evidence have defined the level of type b serum antibody that best correlates with protection. In an unvaccinated population, ≥ 0.15 μg/ml of antibody against the type b capsule correlated with the protection against disease,[252] which is consistent with protective

Table 5. Hib Conjugate Vaccines

Vaccine	Protein carrier	Trade name	Age groups*	Antibody response in infancy
PRP-D**	Diphtheria toxoid	ProHIBiT	15–59 months	Moderate after second dose
HbOC**	CRM197 mutant	HibTITER	2, 4, 6, and 12–15 months	Good after second dose
PRP-OMP	*N. meningitidis* outer membrane protein	PedvaxHIB	2, 4, and 12–15 months	Moderate after first dose
PRP-T	Tetanus toxoid	ActHIB	2, 4, 6, and 12–15 months	Good after second dose
PRP-T/DTaP	Tetanus toxoid	TriHIBit	Licensed for fourth dose only	Not applicable
PRP-OMP/Hepatitis B	*N. meningitidis* outer membrane protein	Recombivax	2, 4, 6, and 12–15 months	Moderate after first dose

* Licensed ages in the United States, **no longer available in the United States

values derived from gamma globulin prophylaxis and from declining maternal antibodies.[262] Among recent recipients of purified PRP Hib vaccine, ≥1 μm/ml antibody predicted long-term protection.[209] While these levels of protection are a useful generalization, they do not take into account the variations in IgG subclass and their distribution in human serum, the idiotype specificity of the antibodies, the antibody avidity, the functional capacity of various types of anticapsular antibodies, the type or intensity of bacterial exposure, or the specific techniques used to measure the antibodies.

9.1.1.3. Use of Current Vaccines. The dose of each Hib conjugate vaccine is 0.5 ml, given intramuscularly. In the United States, the recommended schedule is for all children to receive the primary vaccine series at ages 2 and 4 months for PRP-OMP or 2, 4, and 6 months for PRP-T, with a booster at age 12–15 months. Hib vaccines can be administered separately or in combination with other vaccines.[263] Monovalent Hib conjugate vaccines available in the United States are considered interchangeable for primary and booster immunizations. Two conjugated vaccines are available as combination vaccines, PRP-T/DTaP and PRP-OMP/hepatitis B. All Hib vaccines are safe, with only minor, local reactions occurring in some children. Vaccination with a specific Hib conjugate vaccine is contraindicated in persons known to have experienced anaphylaxis following a prior dose of that vaccine. Minor illnesses (e.g., mild upper-respiratory infection) are not contraindications to vaccination. Vaccination should be delayed in children with moderate or severe illnesses. In premature infants, the immunogenicity of *H. influenzae* type b conjugate vaccines varies widely among studies and may be affected by the type of carrier protein, by inclusion in a combination vaccine, and by an infant's overall health.[264]

Vaccine coverage rates in the United States for the primary series of Hib vaccine (three or four doses, depending on the product used for vaccination) are high, approximately 85%.[265] Use of a combination vaccine is associated with slightly higher coverage, odds ratio = 1.05.

9.1.1.4. Impact of Hib Vaccines. Widespread use of the Hib vaccine in the United States has resulted in dramatic reduction in the number of cases of invasive Hib infections.[266] Figure 3 shows the reduction in cases of Hib meningitis relative to licensure dates and ages of use of Hib vaccines (1) and Figure 4 shows sustained low rates of *H. influenzae* invasive diseases (most of which are caused by type b strains) since the introduction of the vaccines. In spite of the availability of vaccine, however, a small number of children remain undervaccinated; risk factors for failure to receive the complete primary series include having a single-parent mother (odds ratio [OR] = 4.3) and household crowding (OR = 3.5).[267] Among the undervaccinated, living with a smoker and other indicators of lower socioeconomic status such as low family income and low maternal education were independent risk factors for Hib disease.

Mortality rates from Hib meningitis declined rapidly after the introduction of PRP-based vaccines.[268] Prior to introduction of the vaccines mortality rates were approximately 1.5 deaths per 100,000 among children 1–4 years old, and in the year following use of the conjugate vaccines fell to 0.11/100,000 in children ≥2 months old.

Some of the decreased incidence rates and mortality rates of Hib infection are related to the role of conjugate vaccines in reducing colonization of *H. influenzae* type b,[149] likely because of mucosal antibody stimulated by immunization with these vaccines.[269] Similarly, reduced colonization reduces the pool of infectious children in the community, and thus, in communities with high vaccine uptake, the vaccines appear to confer a degree of herd immunity by providing protection for unvaccinated children.

The direct and societal benefit–cost ratios for the Hib vaccination program in the United States have been shown to be 3.4 and 5.4, respectively, resulting in $0.95 billion in benefit from the direct cost perspective and 2.09 billion in benefit from the societal perspective.[270]

9.1.1.5. Vaccine Failures. While undervaccination is the likely explanation for continued Hib infection in the United States, a few fully vaccinated children become infected. Evidence from the United Kingdom showed that vaccine immunity waned following the administration of three doses prior to 4 months of age with no booster at age 2 years.[271] Among British children who developed Hib infection in spite of vaccination, a significantly greater proportion of the infecting strains had increased copy number of the *cap* region, suggesting higher virulence of these strains.[272] In addition, children with antibody deficiency syndromes such as X-linked agammaglobulinemia (Bruton's syndrome), IgG subclass deficiency, or partial antibody deficiency with impaired polysaccharide responsiveness are at increased risk of failure to mount a protective immune response to Hib vaccines.

Following successful introduction of Hib vaccines in Alaskan Natives, re-emergence of invasive disease appeared in 1996[112] and appeared to be related to the use of conjugated vaccines that did not stimulate protective levels of antibody until after the second or third dose. The exclusive use of a product (PRP-OMP) that gave high antibody levels after the first dose subsequently reduced Hib disease rates to low levels in this population. Yet the disease rates among rural Alaskan Native children remain higher than rates in urban Alaskan Natives or other US children, suggesting that equity in disease rates may not be achieved in vaccinated indigenous populations without addressing other environmental and household risk factors.[273]

9.1.2. Antibiotic Prophylaxis Against Hib Infection. Non-immune children under age 4 years who are in close contact with an individual with Hib infection are at increased risk of invasive Hib disease. Because close household and day care contacts of an index case have higher rates of Hib colonization,[274,275] the risk of Hib infection is increased in non-immune children attending a day care or living in a household in which a case of Hib infection has occurred.[276,277] Clinical studies have demonstrated the efficacy of rifampin chemoprophylaxis to reduce Hib nasopharyngeal colonization of close contacts of an index case with Hib disease and, thus, decrease the risk of infection in young, non-immune contact children.[278,279]

The prevention strategy using antibiotic prophylaxis is based on decreasing nasopharyngeal colonization of individuals in close contact with a non-immune child who is at increased risk of Hib infection. Because secondary cases usually occur within a week of the presentation of the index case,[280] prophylaxis should be administered as soon as possible. An index child may be persistently colonized with Hib following treatment with an antibiotic that does not reduce colonization.[281] Table 6 outlines the recommendations for rifampin prophylaxis of close contacts to prevent Hib infection in an at-risk, non-immune child.[263]

Prophylaxis is not indicated in households or day care centers with no at-risk children, such as those with no children <4 years old or with no unimmunized children.

9.2. Vaccines Against NTHi

Because NTHi lack capsular polysaccharide on their surfaces, the Hib vaccines do not protect against infections caused by NTHi. Considerable effort has been directed at identifying bacterial surface antigens for use in a NTHi vaccine[282]; candidate antigens have included the adhesins P5 and the high molecular weight protein, OMP 26, P6, and detoxified lipooligosaccharide. A major barrier to use of many NTHi outer membrane components as vaccine agents is their high level of strain-to-strain diversity. A combination vaccine composed of 11 different *S. pneumoniae* polysaccharides conjugated to protein D, a cell surface lipoprotein of NTHi, as a carrier protein showed only limited efficacy in preventing NTHi acute otitis media, 35.5%, €95% CI 1.8–57.4).[283] Because NTHi primarily cause infections of the respiratory tract, novel approaches to vaccine development, such as direct mucosal application or modulation of specific immune responses, may be required for a successful NTHi vaccine.[284]

Table 6. Recommendations for Rifampin Prophylaxis to Prevent Hib Infection

Household contacts of an index case:

* All contacts (defined as persons residing with the index patient or non-residents who spent four or more hours with the index case for at least 5 of the 7 days preceding the day of hospital admission of the index case) irrespective of age in a household in which an unimmunized or incompletely immunized child <4 years old lives
* All contacts in a household in which an immunocompromised child, regardless of the child's immunization status, lives

Day care center contacts of an index case:

* All contacts in a nursery school or child day center in which ≥ two cases of Hib infection have occurred within 60 days

Index case:

* Index cases treated with an antibiotic other than a third-generation cephalosporin and ≥2 years old or in a household with a non-immune child <4 years

10. Unresolved Problems

The introduction of the conjugated *H. influenzae* type b vaccines has resulted in a stunning reduction in morbidity and mortality from infection caused by *H. influenzae* type b—a remarkable public health achievement accomplished through the collaboration of basic scientists, clinicians, vaccine manufacturers, and public health providers. Challenges remain in achieving high vaccine coverage rates in developing countries and sustaining high coverage rates in industrialized countries. In addition, non-typeable *H. influenzae* continue to cause significant morbidity in the form of acute respiratory infections such as bronchitis, otitis media, and sinusitis. Development of a NTHi vaccine has been elusive and continued efforts to identify appropriate vaccine components to prevent non-typeable *H. influenzae* infections are warranted.

CHAPTER 18

Helicobacter pylori

Sharon Perry, Catherine de Martel, and Julie Parsonnet

1. Introduction

Helicobacter pylori, a corkscrew-shaped, gram-negative rod, resides in the mucous layer of the human stomach. Unrecognized until the 1980s, the organism is extraordinarily common, infecting at least half of the world's population. Once acquired, infection persists chronically, typically continuing in the stomach throughout the host's life. *H. pylori* infection invariably causes acute and chronic gastric inflammation, but in only a minority of cases does it result in overt clinical disease. Yet, the diseases attributed to *H. pylori* infection, peptic ulcer disease and gastric malignancy, are among the world's most important causes of morbidity and mortality in adults. For this reason, the past 30 years have borne witness to furious activity concerning diagnosis, treatment, and prevention of this recently rediscovered pathogen.

2. Historical Background

In 1893 Bizzozero[23] first reported the presence of spiral-shaped organisms in the mammalian stomach. By the 1930s pathologists had linked these spiral bacteria to gastric inflammation and upper gastrointestinal disorders.[57,85,163,253] Later, the organisms were deemed postmortem contaminants, and work on gastric spiral bacteria largely ceased by the 1950s.[239] Some attention continued to be directed to the surprising production of urease within the gastric mucosa, but a specific connection between this enzyme and the previously identified spiral bacterium was not made.[78,178]

In the 1970s, interest in gastric spiral organisms was revived by a few, scattered investigators.[87,302,303] In 1979, Robin Warren, a pathologist in Perth, Australia, began to intensively study the organism and connected it with a common form of gastric inflammation: chronic superficial gastritis.[205] On the strength of this pathological data, Barry Marshall, a gastroenterologist in Perth, treated an infected, dyspeptic patient with tetracycline; the patient's symptoms and histological gastritis completely resolved. From then, Warren and Marshall's research accelerated. By 1982, their group made two major advances: they cultured the organism for the first time (it was named *Campylobacter pyloridis*, but was later renamed *Helicobacter pylori* when taxonomic studies determined it was not a *Campylobacter*) and linked it with peptic ulcer disease.[205] In 1984, after a period of contentious academic debate, Marshall addressed the skeptics by ingesting the organism, thus inducing a self-limited gastritis.[203] Soon thereafter, another investigator repeated the experiment and developed sustained gastric inflammation that did not respond to simple antibiotic regimens.[221] These final experiments convinced most doubters of a role for *H. pylori* in producing gastric inflammation. In 2005, Drs. Marshall and Warren shared the Nobel Prize in Medicine for their pioneering and tenacious work.[202,244]

Since 1984, tens of thousands of articles by thousands of investigators worldwide have been published concerning *H. pylori*. These articles amply document the high prevalence of infection in populations, a causal link to dyspepsia, peptic ulcer disease, gastric cancer, gastric lymphoma, and a protective association with gastroesophageal reflux disease (GERD) and esophageal adenocarcinoma. Numerous studies have shown that many gastric and duodenal ulcers can be cured effectively with antibiotic therapy. As a consequence, in 1994 the National Institutes of Health declared *H. pylori* to be a major cause of peptic ulcer disease and recommended antibiotic therapy as a mainstay of treatment.[42] Others have

demonstrated that *H. pylori* increases risk of gastric cancer at least 4-fold. In 1994, the International Agency for Research on Cancer declared *H. pylori* a group 1 carcinogen (a definite cause of cancer in humans[135]). Most recently, the declining incidence of *H. pylori* infection has been accompanied by a rapid increase in the incidence of esophageal cancers, leading to new speculations regarding protective effects of infection on upper gastrointestinal disease.[252]

3. Methodology

3.1. Sources of Mortality Data

H. pylori does not invade beyond the gastric mucosa and does not directly cause fatalities. There are, therefore, no mortality statistics available for *H. pylori* infection. Diseases associated with *H. pylori* infection, however, do lead to death. Mortality statistics for peptic ulcer disease have not been systematically collected, although several investigators in the United States and Europe have analyzed data from local areas. These data reveal decreasing mortality rates from peptic ulcer disease over time.[166,299–301] The highest mortality has been observed in persons born at the time of the Industrial Revolution, with a gradual decline in risk since. Regional cancer registries throughout the United States[37,357] as well as in other countries[75,157,241,326,355] provide mortality statistics for gastric malignancies.

3.2. Sources of Morbidity Data

H. pylori infection is not a reportable disease. Information on *H. pylori*-related diseases can be obtained from investigator-generated studies and cancer registries.[17,37,141,166,300,322,357] Because dyspepsia is often treated empirically without diagnosis of the underlying pathology, morbidity data for gastric and duodenal ulcers are considered unreliable.

3.3. Surveys

Surveys are the most widely used method for studying the population distribution of *H. pylori* infection. Household, institutional, and population surveys have been conducted in numerous populations worldwide (see Section 5.1). Serological surveys have been the most widely employed cross-sectional design since, in untreated populations, a positive serological test accurately reflects active rather than past infection. Stool antigen and breath tests are also becoming popular as surveillance tools, particularly in studies of children.[14,99,109,278,292,317]

3.4. Laboratory Diagnosis

Both endoscopic and nonendoscopic methods exist to diagnose *H. pylori* infection; none is perfect. The sensitivity and specificity of the diagnostic methods and their respective pros and cons are listed in Table 1.

3.4.1. Isolation and Identification. *H. pylori* is a relatively fastidious organism that does not thrive outside of its natural environment. Despite this, the organism can be cultured from gastric mucosa if proper measures are taken. Biopsies obtained from the stomach should be rapidly placed in transport medium (such as Stuart's medium with chocolate or broth with supplemental serum) to prevent desiccation. Ground gastric biopsy specimens should then be plated on a solid medium as soon as possible.[123] Delay in culture mandates freezing of the biopsy specimen at 4°C until the time of plating. *H. pylori* requires an enriched environment

Table 1. Diagnostic Tests for *Helicobacter pylori* Infection

Test	Sensitivity (%)	Specificity (%)	Comments	Cost	Reference
Endoscopic					
Histology	90–95	95–98	Based on at least two antral biopsies	$$$	[226, 332]
Culture	70–92	100	Technically demanding; best reserved for research	$$$	[35, 225]
Rapid urease test	88–97	93–98	Endoscopic method of choice for diagnosis	$$$	[167, 212]
Noninvasive					
^{13}C or ^{14}C breath test	>95	>95	^{13}C for children and pregnant women; good for patient follow-up	$	[38, 95, 107]
Stool antigen test (polyclonal – monoclonal)	91–96	93–97	Good for children and for patient follow-up	¢¢	[94, 96]
Serology	80–99	87–96	Good for surveillance; not good for short-term follow-up or children <2 years	¢	[67, 69, 73]

for growth. Many agar bases will sustain the organism if supplemented with blood or serum; antibiotic supplementation in the medium may minimally increase culture sensitivity. Plates should be incubated at 37°C under microaerophilic conditions (10% CO_2 with 98% humidity).[123] *H. pylori* grows slowly and plates may require 7 days incubation to develop recognizable colonies. Presumptive identification can be made if organisms have typical gram-negative, curved morphology on Gram's stain and produce both catalase and urease. In research settings, a more definitive diagnosis can be made with molecular probes and/or electron microscopy.

On rare occasions, *H. pylori* has been cultured from stool and saliva[162,248,321] which is not routinely effective. Another experimental method of obtaining isolates is a gastric "string test," for which sensitivity has been quite variable.[176,284,337]

Culture is the least sensitive but most specific method for diagnosis of *H. pylori*. It is particularly insensitive in laboratories with little experience.[225,332] Because other diagnostic tests are widely available, culture is best reserved for research laboratories with an interest in obtaining isolates for research and/or antimicrobial sensitivity testing.

3.4.2. Other Endoscopic Methods of Diagnosis. Histology is still considered by many to be the "gold standard" for diagnosis. Not only does it reliably identify infection, but it also can provide information on underlying gastric pathology. Because *H. pylori* is not evenly distributed throughout the gastric mucosa, however, at least two biopsies need to be performed to sensitively diagnose infection.[220,226] Routine hematoxylin and eosin staining will usually reveal the organism; the more sensitive but more expensive silver stains should be reserved for inconclusive examinations.[35]

Another commonly used endoscopic test is the rapid urease test. This method exploits the organism's rapid hydrolysis of urea to ammonia and carbon dioxide. A biopsy of the stomach is obtained and placed in a urea-containing medium with a pH indicator. Production of ammonia turns the indicator red and confirms the presence of the organism. The rapid urease test can often be interpreted in less than 1 hour and is substantially less expensive than histology. Nonetheless, it does require endoscopy. Reported sensitivity and specificity of rapid urease tests vary considerably from study to study.[175,206,208] Most, however, show approximately 90% sensitivity with even greater specificity.[167,212]

3.4.3. Nonendoscopic Diagnostic Tests. Three noninvasive methods of diagnosing *H. pylori* are widely used: serology, breath test, and stool enzymatic immunoassay (EIA). The usual serologic assays are quantitative enzyme-linked immunosorbent assays (ELISAs) that measure serum IgG titers against *H. pylori*-specific antigen. In untreated patients—including patients treated with single antibiotics for other purposes—IgG response to *H. pylori* infection is stable over the years, reflecting the chronic nature of infection even in the face of routine antibiotic use.[245] Conversely, 6 months following successful eradication therapy against *H. pylori* infection, antibody titers typically decrease at least 50%.[48,161] This drop in titer appears to be quite sensitive and specific for successful treatment. Unfortunately, a single serum obtained following therapy will not necessarily become quantitatively negative, limiting the use of serologic tests in previously *H. pylori*- treated subjects.

Numerous commercial serologic tests—including in-office rapid tests— are available; the antigens used vary from kit to kit as may the simplicity of the assay methods. Consequently, sensitivity and specificity also vary[73,182]; some kits perform inadequately.[9,332] At their best, in adults and older children, ELISA kits have sensitivity and specificity for active infection exceeding 90% and sometimes exceeding 95%. Sensitivity is considered unreliable in very young children.[50,55,122,148] ELISAs may also have varying performance from population to population, perhaps due to differences among the *H. pylori* strains used for the ELISA and those found in the population.[9,31,52] For these reasons, serological tests should be evaluated in the intended population before being used for epidemiological or clinical purposes.

Serologic tests to measure IgG antibodies against the CagA protein of the pathogenicity island (see Section 7) have also been developed.[22,46] These tests, which target the 128 kDa protein of the *cagA* pathogenicity island (Section 4), have become important in epidemiologic surveys of populations at risk of more virulent outcomes such as gastric cancer, but are less useful in the clinical setting.

Carbon-labeled urea breath tests have become increasingly popular for clinical diagnosis as well as in epidemiologic surveillance. Now approved by the US FDA for use in routine diagnosis, these tests exploit the organism's production of urease to detect active infection following oral administration of ^{13}C- or ^{14}C-labeled urea.[95,156] If *H. pylori* is present in the stomach, the ingested urea is metabolized into ammonia and labeled CO_2. Using either mass spectrometry (^{13}C) or scintillography (^{14}C), the amount of excess CO_2 relative to other carbon isotopes may be measured in the exhaled air of an infected patient within half an hour. Although there is no evidence that the amount of radiation exposure associated with use of the ^{14}C breath test (about 1 uCi residual) is unsafe, the test is contraindicated in pregnant women and children.[38] The ^{13}C breath test uses a stable carbon isotope and is appropriate for use in these groups. Though more expensive than serology,[119,334] the

tests' high sensitivity and specificity make them potentially valuable in surveillance work, as well as in many clinical situations, including pre-endoscopic screening, antibiotic eradication management, and following surgical resection.[39,95] Because false-negative results are possible if the patient has been taking antibiotics, proton pump inhibitors, antacids, or antihistamines that decrease gastric acid secretion,[110] clinicians must be alert to circumstances that make the tests most informative. Several factors, including type of test meal, dosage, type of urea, and clinical (pre- or post-treatment) indication may influence choice of cut-off values for qualitative interpretation.[95] For use in small children, correction for body mass-dependent CO_2 production may improve validity.[155]

Enzymatic immunoassays to detect the presence of *H. pylori* antigen in stool have now become commercially available. A rapid anti-*H. pylori* antibody capture, the test can be performed on fecal samples at room temperature with a colorimetric result obtained in 1–2 hours for the laboratory kits and in a few minutes for some of the new in-office products. In untreated patients, one systematic review estimated weighted sensitivity and specificity, which are often evaluated against the ^{13}C urea breath test, at 91% and 93%, respectively.[96] In a EUROGAST study of 501 untreated patients, sensitivity and specificity were 94% and 92%, respectively, by stool antigen test versus 95% and 98% by breath test when both were evaluated against a combination of biopsy-based culture and urease test.[333] Both polyclonal and monoclonal antibody conjugates are available, with the latter considered somewhat more accurate.[94,128,290] Although considered promising for use in small children, relatively few studies have focused on this population. In 127 children aged 4 months to 17 years, overall sensitivity and specificity of the polyclonal antibody were 95% and 97%, but 80% and 96%, respectively, in children 2–6 years of age; no infants under 2 years of age had positive tests.[269] In a small pediatric series, stool antigen was correlated with non-specific *Helicobacter* sp. DNA amplification of stools. Among 15 sequences from stools 3 were non-*pylori Helicobacter* species,[118] indicating both colonization of children with other species and lack of test specificity.

The stool antigen tests have been evaluated for use in post-treatment evaluations. According to one review of studies in which at least two reference standards were used, positive and negative predictive values were 77% and 89%, respectively, when performed 4–8 weeks following treatment.[97] In Japan, diagnostic accuracy of the stool antigen test was 97%, versus 94% by ^{13}C breath test, in 105 patients evaluated at least 8 weeks post-eradication.[312] As with the breath test, recent use of proton pump inhibitors may be a cause of false-negative results.[128] Stool sample may be stored at 2–8°C for 3 days and at −20°C indefinitely. The relative simplicity and cost-effectiveness of the test make it a useful addition to epidemiologic and clinical investigations, particularly in evaluating populations without frank indications for endoscopy.

Polymerase chain reaction (PCR) can sensitively detect *H. pylori* DNA in the saliva, dental plaque, or gastric juice of persons with gastric infection but is considered primarily a research tool.[34,199,228]

4. Biological Characteristics of the Organism

The genus Helicobacter, recognized with the rediscovery of *H. pylori*, comprises a diverse group of curved, spiral bacteria that colonize the gastric and intestinal tracts of animals as well as humans.[346] Adapted to the human stomach, *H. pylori* is a neutralophilic spiral-shaped, gram-negative rod 2.4–4.0 μm long and 0.5–1.0 μm wide possessing 2-6 flagellae at one end that provide it with corkscrew motility. Under stress, *H. pylori* loses its spiral morphology and first becomes more simply curved and eventually coccoid. Some believe the coccoid forms to be metabolically active, transmissible, but noncultivable, forms of the organism; most recent data, however, suggest that coccoid forms are not viable.[30,64,283]

Approximately 30 different outer membrane proteins (HOPs) have been identified, of which several, most notably BabA, have been implicated as adhesins.[5,25,187,267,291] Expression of adherence factors may be adaptive, with the organism able to exploit both phase variation and host antigenic variation to regulate attachment.[336] In any event, adherence may be necessary to prevent elimination during gastric emptying.

As a neutralophile, *H. pylori* grows optimally at a pH between 6.0 and 8.0. Although it can survive in artificial media at pH of 1.5 if given supplemental urea,[204,305] under more relevant conditions, it is unable to survive at pH $<$ 3.0, or to grow at pH $<$ 6.0 or above 8.3.[281] While many neutralophilic gram negatives can survive acid shocks (pH $<$ 3.5) during transit of the stomach, *H. pylori* is unique in its ability to colonize this environment. It appears to do this, at least in part, through prodigious production of urease, which it produces far in excess of other neutralophiles.[219] Accounting for 10–15% of proteins by weight, this enzyme, a 300- to 625-kDa nickel-containing hexamer, hydrolyzes urea to CO_2 and ammonia.[329] Crystallography has revealed a large 1.1 MDa supramolecular assembly consisting of 12 catalytic units active to a pH of 3.[117] Urease is primarily a cytoplasmic protein,[286] although it may also be found on

the surface of the bacteria due to lysis or other mechanisms that are poorly understood.[201,281,304]

The physiologic role of *H. pylori* urease appears to be both novel and complex. In animal models, urease is essential for *H. pylori* colonization of the stomach,[10,63,328] and in gene expression studies survival of acid shocks <3.0 depend on urease production.[336] The *H. pylori* urease gene cluster consists of seven essential genes, organized into two primary segments, UreA and UreB, and five accessory genes,[3] with regions of UreB appearing to differ significantly from other known urease.[117] Commonly thought to be constitutively expressed,[281] recent evidence suggests that urease activity may be more controlled.[304] The UreI protein, a proton-gated urea channel that may be unique to *H. pylori*, now appears to play a critical role in generating a rapid urease response to shifting micro-environmental conditions.[262,344] However, since urease production accounts for a considerable portion of the organism's energy expenditure, *H. pylori* urease probably serves other essential functions. Damage to the gastric mucosa induced by urease and/or ammonia may provide the organism with necessary nutrients or an environment appropriate for attachment and growth. Alternatively, urease-induced ammonia may provide protection from the innate immune system and may also be important for nitrogen assimilation by the organism.[90,347] Urease may also disarm the innate immune system during early stages of infection.[101] Nonurease genes may also be involved in acid regulation.[345] This suggests a tightly coordinated and adaptive acid resistance system.[282]

One of the most important developments of the past two decades has been the identification of the Cag pathogenicity island (PAI), named after one of its proteins—the 128 kDa CagA (cytotoxin-associated gene A) protein—that elicits a strong IgG response and thereby serves as a marker for the presence of the PAI.[24] Found in approximately 60–70% of US isolates the PAI is a large chromosomal cassette flanked by 31 base pair DNA repeats that encode a type IV secretion system (TFSS) that in addition to promoting adhesion[124] and translocation[238,250] is involved in disruption of signaling pathways of epithelial cells.[8,25,251,287]

Another important protein of *H. pylori* is its vacuolating cytotoxin which is encoded by the VacA gene. This 88-kDa secreted protein has structural homology with the IgA proteases of *Neisseria* and *Haemophilus*.[285] It received its name from the vacuole formation it induces in tissue culture cells.[45] In mouse models, oral administration of purified cytotoxin not only induces vacuolation of gastric mucosal cell but also results in inflammation and gastric ulceration.[318] Recent studies have suggested that the p55 domain plays an important role in epithelial binding.[43] All strains of *H. pylori* possess the cytotoxin (*VacA*) gene, although expression of a functional, virulent protein occurs in only 50% of strains.[44] Strains possessing VacA alleles of the type s1/m1 form appear to have the greatest vacuolating activity[43]; such alleles are typically found in isolates with a PAI.

H. pylori strains exhibit enormous genetic diversity.[4,26,133,314] *H. pylori* has been completely sequenced twice[6,233,324] and has a 4.5 kb genome with approximately 1,400 informative sites. Overall, only 94% of genetic content was shared by J99 and 26695, and 7% constituted by genes unique to one or the other.[6] One group sequenced 370 gene fragments in 27 geographically separate populations, finding that of 1,531 genes present on average, only 1,111 existed in all strains.[115] By fingerprinting methods, it is unusual to find identical strains in different subjects. In one report, clinical isolates were obtained from the same patient 6 years apart. Compared with the original J99 strain, sequencing of the new isolates revealed 3% variation compared with 22% when isolates of different individuals were compared.[139] In another report using whole-genome DNA microarray to compare 21 pairs of isolates taken from the same patient over time, the majority of genetic changes were classified as homologous events, rather than net loss or acquisition of genes.

The tendency for frequent recombination involving relatively short fragments makes the organism useful for ancestral genetic studies. Strain variants deduced from phylogenetic models appear to parallel the major routes of human migrations in modern times.[70,147] The PAI appears to bear the signature of a relatively recent horizontal acquisition.[26] Thus, *H. pylori* may have been colonizing humans since the origins of modern civilizations, utilizing genetic variation to adapt to individual hosts as well as populations.

Though *H. pylori* is by far the most important helicobacter in humans, some non-*H. pylori* helicobacters may also colonize humans.[83]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

H. pylori has been present in humans for tens of thousands of years[70] and still infects half the world's population. Acquired primarily in childhood, the infection persists throughout life. Many seroprevalence studies of *H. pylori* have been conducted worldwide and the organism has been found wherever it has been sought. Prevalence of infection, however, varies widely between and within population groups. Prevalence in developed countries

has been declining in recent decades and is considerably lower than in developing countries. Prevalence of infection within populations also varies with age and socioeconomic status.

Figure 1 compares age-specific prevalence rates from several selected population-based studies. In developing countries (Section A), a majority of the population is infected by age 10 years. In developed countries (Section B), prevalence of *H. pylori* is lower. Infection in children in these countries is now rare, except in immigrants from poorer regions of the world.[16,62,255,258,327] Of course, there are some exceptions to these two main patterns. For instance, a seroprevalence survey conducted in a small isolated Nepalese village showed a low rate of infection, despite the low socioeconomic level and the poor level of hygiene and sanitation.[145] Within countries, the proportion of infected patients with antibodies to CagA appears to be relatively constant with respect to age and gender.[254]

Because acute *H. pylori* infection virtually always passes undiagnosed, incidence cannot be estimated from clinical data. However, some information on incidence can be gleaned from longitudinal seroprevalence surveys. In some surveys, an exponential increase in seroprevalence with age suggests a steady incidence of infection over time.[242] For example, in whites from the United States, prevalence data correspond closely to a 1% per year rate of infection. In contrast, prevalence in one African-American population conformed to an incidence of 3% per year.[109,242] Most prevalence data, however, do not support a constant incidence rate.

Because of the difficulties in determining incidence based on clinical illness or prevalence data, investigators have repetitively tested for *H. pylori* infection in population cohorts followed over time (Table 2). Despite differences in study design, the data from developed countries are relatively consistent in their estimations of seroincidence. In adults (Table 2A), a mean of 0.4% of subjects converted from *H. pylori* seronegative to seropositive per year.[242] Coincidentally, the seroincidence rate observed in prospective studies of adults closely matches the incidence of reinfection seen in treated patients. This suggests that prior infection with *H. pylori* neither protects against nor predisposes to reacquisition of the organism. In studies evaluating children (Table 2B), incidence rates are higher than in adults, with the highest rates of acquisition observed around age 2 years and most infections acquired by age 5 years.[113,188,277,280] In very young children from high-risk groups, frequent transient infections (a positive test followed by a negative test) before the age of 2 years have also been reported.[104,153,256,277,320] What proportion of these phenomena represents true transient infection versus single false positives in subjects with low pretest probability remains controversial.[234,260,276]

[a]Adapted and expanded from Parsonnet, J. (1995). The incidence of *Helicobacter pylori* infection, *Aliment. Pharmacol. Ther*, *9*(suppl. 2), 45–51.
Note: Serology: IgG antibody test; UBT: ^{13}C urea breath test; Stool: stool antigen test

5.2. Age and Birth Cohort

In Western countries, older age groups consistently exhibit higher prevalence of infection than younger generations. A disproportionately high prevalence of *H. pylori* infection among older persons may reflect one of three phenomena: an age effect (higher acquisition of infection at older ages), an age cumulative effect (steady incidence of infection throughout life), or a birth cohort effect (older individuals may have been born in times when risk of infection was greater). A birth cohort effect explains better how low incidence rates documented in recent prospective trials can be reconciled with high cross-sectional prevalence. Numerous cross-sectional studies that examined populations over time demonstrated a decreasing prevalence of *H. pylori* infection with increasing birth year.[160,165] It is now generally agreed that *H. pylori* incidence has decreased over time in industrialized countries in parallel with improving hygiene and socioeconomic status.

As mentioned above, prevalence of *H. pylori* infection increases with age in all population groups. An exception to this is seen in the advanced elderly, particularly in developing countries. Serosurveys suggest that the very old may have lower prevalence of *H. pylori* than younger persons.[315] It has been speculated that this is due to advanced atrophy lesions that occur with older age. Since *H. pylori* can only survive adjacent to gastric epithelium, destruction or replacement of gastric mucosa by metaplastic intestinal epithelium might result in loss of infection.[92]

5.3. Gender

Men have higher rates of both duodenal ulcer disease and gastric cancer than do women. Yet, while *H. pylori* infection is thought to cause both diseases, studies have shown conflicting results when comparing *H. pylori* prevalence between genders. A recent meta-analysis of previously published large population-based studies showed a small but significant and homogeneous elevated risk of infection among adult men concordant with their elevated risk for *H. pylori*-related diseases. This male predominance was not apparent in studies of children.[54] This finding portends either a greater loss or greater acquisition of infection in female adolescents or young adults.

5.4. Race–Ethnicity

Serosurveys of *H. pylori* infection have identified pronounced differences in prevalence among racial/ethnic

population groups. In the United States, higher prevalence of *H. pylori* has been reported in African-American and Hispanic populations compared to non-Hispanic white populations.[109,129] In the largest and most representative study—a cross-section of the US adult population with overall prevalence of 33% (NHANES III, 1988–1991)—age-adjusted seroprevalence was 62% in Mexican-Americans, 53% in African-Americans, and 26% in non-Hispanic whites.[68] Outside of the United States, racial–ethnic variations in *H. pylori* prevalence also have been observed. In Taiwan, the highest seroprevalence (63.4%) was found in a rural indigenous population and the lowest (40.5%) in an urban area inhabited primarily by Hakkas.[317] The indigenous Maori of New Zealand also have higher (39–70%) infection rates than white New Zealanders (15%).[222] This discrepancy, though consistent, has varied in magnitude with the age and other characteristics of study populations.[84,254] Although an early study found the opposite,[59] Western Australian aborigines may have infection rates two to three times higher than non-indigenous Australians.[348] In Belgium, non-Caucasian children were more likely than Caucasian children to be infected.[28] Similarly, in Malaysia, a country of diverse Asian races, Malays were reported to have significantly lower infection rates than Chinese or indigenous Indian groups.[102] Although comparative studies are lacking, indigenous populations of the Americas, where studied, may have much higher rates of infection than non-indigenous groups.[21,256,274]
